## 12 **Highlights**

- 13 • Numerical models improve the appraisal of the slip rates in central Italy
- 14 • The model slip rates vary with depth and differ for each fault
- 15 • Mean slip rates are  $\sim 1.1$  mm/yr for normal faults and  $\sim 0.2$  mm/yr for thrust faults
- 16 • 100 years after a large earthquake, the Avezzano fault is half unlocked at depth

## 17 **Abstract**

18 Slip rate is a critical parameter for describing geologic and earthquake rates of known active faults.  
19 Although faults are inherently three-dimensional surfaces, the paucity of data allows for estimating only  
20 the slip rate at the ground surface and often only few values for an entire fault. These values are frequently  
21 assumed as proxies or as some average of slip rate at depth. Evidence of geological offset and single  
22 earthquake displacement, as well as mechanical requirements, show that fault slip varies significantly with  
23 depth. Slip rate should thus vary in a presumably similar way, yet these variations are rarely considered.

24 In this work, we tackle the determination of slip rate depth distributions by applying the finite  
25 element method on a 2D vertical section, with stratification and faults, across the central Apennines, Italy.  
26 In a first step, we perform a plane-stress analysis assuming visco-elasto-plastic rheology and then search  
27 throughout a large range of values to minimize the RMS deviation between the model and the interseismic  
28 GPS velocities. Using a parametric analysis, we assess the accuracy of the best model and the sensitivity of

29 its parameters. In a second step, we unlock the faults and let the model simulate 10 kyr of deformation to  
30 estimate the fault long-term slip rates.

31         The overall average slip rate at depth is approximately 1.1 mm/yr for normal faults and 0.2 mm/yr  
32 for thrust faults. A maximum value of about 2 mm/yr characterizes the Avezzano fault that caused the  
33 1915, Mw 6.9 earthquake. The slip rate depth distribution varies significantly from fault to fault and even  
34 between neighbouring faults, with maxima and minima located at different depths. We found uniform  
35 distributions only occasionally. We suggest that these findings can strongly influence the forecasting of  
36 cumulative earthquake depth distributions based on long-term fault slip rates.

## 73 1 Introduction

74 Fault slip rate is a fundamental quantity in studies on rock mechanics, tectonics and geodynamics,  
75 and seismic hazards. In the latter, slip rate is used to predict earthquake rates of the major active faults.  
76 However, geologically-derived slip rate is often an elusive quantity because its estimation requires that  
77 both the amount and age of the offset features be known. In most field studies, one or a few data points  
78 are commonly accepted as representing some presumed average displacement along the fault strike, and  
79 the time component is often associated with significant uncertainties and may span considerably different  
80 time frames (i.e., from a few tens to hundreds of years in the historical record, to tens of thousands of  
81 years in paleoseismology, to millions of years in some geologic studies). Numerical models provide more  
82 comprehensive estimates of fault slip rates when an independent method that includes the overall  
83 deformation, both on- and off-fault strain, is necessary. Geological restoration algorithms (as the trishear,  
84 Hardy and Ford, 1997; Allmendinger, 1998) work well when the fault geometry and the embedding  
85 chronostratigraphic units are adequately known (e.g., Gold et al., 2006; Maesano et al., 2015). Conversely,  
86 finite-element modelling is especially advantageous when the rock mechanical and rheological properties  
87 are well known. Finite-element models may incorporate various degrees of complexity of the structure  
88 under study. For example, Bird (1989, 1999) developed the program SHELLS for modelling a two-layer crust  
89 and lithospheric mantle, incorporating faults, lithospheric and rheological characteristics, laterally varying  
90 thermal structure, and geodynamic boundary conditions. This approach has been already applied in various  
91 cases and tectonic settings (e.g., Geist and Andrew, 2000, for California strike-slip faults; Bird, 2009, for  
92 active faults in the western US; Kastelic and Carafa, 2012, for thrusts and strike-slip faults in the Dinarides).  
93 Finite element models with mechanical layering and variable rheology have also been used to reproduce  
94 the long-term regional state of stress and strain or the forces that act on faults (e.g., Vergne et al., 2001;  
95 Hsu et al., 2003; Chamlagain and Hayashi, 2005; Carafa and Barba, 2011; Trubienko et al., 2013; Carafa et  
96 al., 2015). In more general terms, two main strategies can be followed to determine fault slip rates through  
97 numerical models: 1) the amount of slip is imposed on the fault plane (e.g., Ward and Valensise 1996;  
98 Hardy and Ford, 1997; Wang et al., 2006), or 2) the fault under the drive of tectonic forces is left to slip  
99 freely (e.g., Cowie et al., 1993; Bird, 1999). In both cases, the correct amount of slip rate is found by fitting  
100 the model results to a given set of deformation data. Geologic field studies and numerical models often rely  
101 on deformation data collected from the ground surface or shallow geologic probing. Such slip rate  
102 determinations thus exploit the effect onto the free surface of the actual slip on the fault plane at depth.  
103 Therefore, those values are often assumed to be the same as, or the average of, the slip rate at depth.  
104 However, knowing the slip rate distribution at depth, rather than just its inferred average, can be useful for  
105 improving our understanding of Earth's crust behaviour and bettering our estimates of earthquake rates.

106 In this work, we use finite-element models to calculate the slip rate distribution at depth. To this  
107 end, we set up a 2D-cross-sectional multilayer finite-element model in the central Apennines, Italy. The  
108 Apennines is an example of a youthful extensional system that progressively overprints an older  
109 contractional belt. More specifically, the contractional fold-and-thrust system migrates toward the east and  
110 is replaced by extension to the west (Elter et al., 1975), and the contraction and extension systems coexist  
111 at short distances from one another (e.g., Negrodo et al., 1999; Pondrelli et al., 2008). Among the  
112 numerous active normal and thrust faults in the central Apennines, several are deemed to be seismogenic  
113 (Figure 1), and a few of them have actually generated damaging earthquakes in the last century or so (e.g.,  
114 Avezzano 1915, Mw 6.9; Colfiorito 1997, Mw 6; L'Aquila 2009, Mw 6.3 for normal faulting; Senigallia 1930,  
115 Mw 5.8; Porto San Giorgio 1987, Mw 5.1 for thrust faulting).

116 As regards normal faults, several attempts using geological field data provided vertical throw rates  
117 in the range of 0.1 to 1.0 mm/yr (e.g., Roberts et al., 2004; Papanikolaou et al., 2005) and slip rates in the  
118 range of 0.2 to 1.3 mm/yr (e.g., Benedetti et al., 2013) derived from exhumed bedrock fault scarps. Similar  
119 values were obtained from broader Quaternary geologic data on intermountain basins by Pizzi et al. (2002).  
120 A few higher slip rates were instead proposed from paleoseismic trenching, such as the 1.6 mm/yr for the  
121 Fucino fault (Michetti et al., 1996), and the 2.5 mm/yr for the Ovindoli-Pezza fault (Pantosti et al., 1996). All  
122 these estimates are based on surface data. The unwieldy relationships between the actual faults at depth  
123 and their surface expression during earthquakes (e.g., Bray et al., 1994) or the plasticity of the material and  
124 the effect of gravity loads (e.g., Albano et al., 2015) are rarely considered in these types of study. Such  
125 complexities were noted on the occasion of recent earthquakes in central Italy, for example, by Barba and  
126 Basili (2000) and Chiaraluce et al. (2003) for the Colfiorito earthquakes of 1997 and Bonini et al. (2014) for  
127 the L'Aquila earthquake of 2009. Based on analogue models, Bonini et al. (2015) also showed that the  
128 growth and evolution of normal faults in the presence of inherited discontinuities, such as the detachments  
129 and thrust faults in the Apennines, can largely deviate from the ideal behaviour in isotropic conditions.  
130 Apennine thrust faults provide examples of slip rates directly derived from crustal depth deformation data.  
131 Visini et al. (2010) provided bulk horizontal contractional rates of 0.09 to 0.31 mm/yr for the outer  
132 Apennines belt based on seismicity. Using numerical methods of geological section restoration, Maesano et  
133 al. (2013) and Bigi et al. (2013) provided estimates of very long-term (2-5 My) average slip rates of some  
134 coastal and offshore thrust faults in the range of 0.26 to 1.35 mm/yr and 0.15 to 2.62 mm/yr, respectively.  
135 However, all of them are depth-averaged values.

136 Considering this tectonic context and the scale of the problem to tackle, we made a selection of the  
137 main active faults in the region (Figure 1) and included them in the model with a simplified geometry. The  
138 faults cut through a specially designed geological section obtained by combining several publicly available  
139 geological data at the regional scale of the model. We initially established a first-order deformation pattern  
140 that allowed us to compute the long-term slip rate at depth for all the fault planes under the free-slip

141 condition. We let gravity and tectonic forces deform the model, and then varied several model parameters  
142 and faults in order to fit the geodetically-derived velocity field. Using the best model found in the previous  
143 step and testing several faults combinations, we then calculated the long-term fault slip rate at depth. We  
144 concluded that slip rate can vary significantly with depth and that this variation can take different shapes  
145 among the faults. We also found, among the various possible solutions, that some faults move oppositely  
146 from their geologically defined kinematics. The resulting average slip-rate values for our preferred option  
147 with respect to geologically-derived slip rates are systematically higher for normal faults and lower for  
148 thrust faults.

## 149 **2 Data and methods**

150 In this study, we constructed a 2D multi-layered finite element deformation model that combines  
151 visco-elasto-plastic rheology, discontinuities (detachments and faults), and gravity (Figure 2). The model  
152 section was chosen to be parallel to the principal stress components as indicated by SHmax (e.g. Carafa and  
153 Barba, 2013) and axes of focal mechanisms (e.g. Pondrelli et al., 2011) in the area so that we could conduct  
154 plane-stress analysis, where the out-of-plane stress is zero. The model was used to simulate the  
155 interseismic deformation and to derive the long-term slip rate of the embedded faults. In both analyses,  
156 the model performance was established by comparing the model output in terms of velocity field at the  
157 free surface with a reference velocity field derived from geodetic data. Since the a priori information about  
158 the model properties at the needed scale is generally affected by significant uncertainties, we set up an  
159 initial model based on information derived from the literature and then performed a trial-and-error  
160 procedure and a parametric analysis to search for the model geometry and parameters of layers, presence  
161 and locking of discontinuities, and boundary conditions that best fit the reference velocity field in the  
162 interseismic period. Considering that all the faults included in the model are deemed to be active in the  
163 recent geological time, the best model then served as a reference for calculating the long-term slip rate at  
164 depth by unlocking all the faults. The epistemic uncertainty in the actual presence and activity of faults was  
165 explored by including different fault sets in the slip rate calculations. The numerical analysis was performed  
166 using the MSC/Marc-Mentat finite element suite (2013; MSC Software Corporation,  
167 <http://www.mscsoftware.com/>).

### 168 **2.1 Reference geodetic velocity**

169 For the surface horizontal velocity field in the study area, we adopted a solution based on GPS  
170 motion with respect to a fixed Eurasian frame (Devoti et al., 2011). The used GPS data span the period from  
171 1998 to 2009, which includes the L'Aquila earthquake (April 6th, 2009). The coseismic and postseismic  
172 displacement components of this earthquake were modelled and corrected in the dataset by the GPS  
173 analysts, along with the evaluation of seasonal variations and changes in the station equipment (Devoti et

174 al., 2011). These geodetic velocities thus represent the interseismic velocity field. We selected the  
175 horizontal velocities for our model from GPS stations located within a 200-km-wide swath along the model  
176 section (Figure 3a). The section-parallel component of the horizontal velocity is shown in Figure 4. The  
177 section-normal component of the horizontal velocity represent an out-of-plane motion that is not modelled  
178 here.

179         Given the lack of GPS data in the Adriatic offshore, to constrain the eastern sector of the velocity  
180 field we considered that the Adriatic domain is undergoing compression. This stress condition in the  
181 Adriatic domain is supported by the seismic moment tensors (Figure 3a): the extensional regime which  
182 dominates the western and the inner parts of the chain gives way to the contractional and transcurrent  
183 regimes toward the east (Frepoli and Amato, 1997; Pondrelli et al., 2008) as indicated by a few compressive  
184 earthquakes generated in the Apennines northeast-verging thrusts (such as those of Senigallia, 1930, Mw  
185 5.6, described by Vannoli et al., 2015, and Porto San Giorgio, 1987, Mw 5.1, described by Riguzzi et al.,  
186 1989) and a few caused by Dinarides southwest-verging thrusts (as the Jabuka Island, 2003, Mw 5.5,  
187 described by Herak et al., 2005, along with few other smaller compressive earthquakes). All these  
188 earthquakes have a roughly NE-SW trending compressive axis. We thus fixed a point at approximately 30  
189 km to the northeast of the model section (to include the Apennines and Dinarides thrusts facing off against  
190 each other) as a zero-velocity reference (Figure 3b) and then interpolated the velocity data through an  
191 asymmetric double-sigmoid function, via robust weighting of residuals, and resampled the profile at a 1-km  
192 spacing to construct the horizontal velocity curve and the associated 95% confidence interval (Figure 4).

193         From SW to NE, three main sectors can be outlined: 1) 0-110 km; 2) 110-150 km; 3) 150-200 km.  
194 The first sector is dominated by extension. The velocity curve indicates low rates in the southwestern part  
195 and higher rates, peaking at almost 3.0 mm/yr, toward the northeast. The largest extension occurs in the  
196 steeper gradient zone at approximately 80 km. The second sector is characterized by a transition from  
197 extension to contraction. This change takes place where the velocity is highest but starts decreasing, and  
198 where the associated confidence interval is still rather narrow. The third sector includes the part of the  
199 velocity curve that is constrained to satisfy the null velocity at the outer thrust front. Here the velocity  
200 tapers to 0.3 mm/yr toward the model eastern edge. Notice that in this region, the confidence interval  
201 enlarges dramatically because the interpolated velocity is not directly derived from GPS data.

## 202 **2.2 Numerical model setup**

### 203 **2.2.1 Model geometry**

204         To draw the geological layers that make up the numerical model geometry (Figure 2), we used the  
205 geological interpretations of CROP-11, a 256-km-long deep seismic line across the central Apennines (Figure  
206 1), from Patacca et al. (2008) and Di Luzio et al. (2009). Patacca et al. (2008) interpreted only the eastern  
207 half of the profile showing that the Precambrian crystalline basement and a thick Paleozoic-Triassic

208 sedimentary sequence underlie the Mesozoic-Cenozoic Apulia and Apennine carbonates. Di Luzio et al.  
209 (2009) combined wide-angle refraction profiles, Bouguer gravity anomalies, receiver functions, and  
210 interpreted seismic reflection data to determine the Moho depth along the entire CROP-11. They proposed  
211 that the point of intersection between the Tyrrhenian and Adriatic plates at Moho depth (hereinafter called  
212 ITAM) could have two possible positions beneath the central Apennines. They also identified five major  
213 crustal layers, namely the Apulia carbonates, the Apennine carbonates, the upper and lower parts of the  
214 Paleozoic-Triassic sequence, and the Adriatic lower crust. Also, they suggested the presence of a  
215 detachment between the upper and lower parts of the Paleozoic-Triassic sequence. Below the crust, the  
216 Tyrrhenian side presents a hot asthenosphere related to the oceanic thinning, whereas the Adriatic side  
217 exhibits a seismic lid (e.g., Doglioni et al., 2007).

218 After combining the various sources of geological information summarized above, we devised a  
219 200-km long and 40-km-thick model section with a simplified stratigraphy initially composed of seven layers  
220 (Figure 2). From top to bottom, they are as follows. S1 and S2 represent the upper crust corresponding to  
221 Apennine and Adriatic (Apulian Platform) Meso-Cenozoic carbonates and terrigenous units. S3 and S4  
222 represent the intermediate crust, corresponding to the Paleozoic-Triassic sedimentary sequence and the  
223 crystalline basement. Notice that S4 is composed of two different bodies, with the same parameters,  
224 separated along the Tyrrhenian-Adriatic dipping boundary. S5, S6, and S7 represent the Tyrrhenian  
225 asthenospheric wedge, the lower crustal of the Adriatic slab, and the lid, respectively. The ITAM is  
226 approximately located under the Fucino basin and can take several alternative positions. The model  
227 geometry also includes a few major discontinuities representing active and potentially seismogenic faults  
228 for which the slip rate distribution will be calculated and horizontal to gently dipping detachments (see  
229 Table 1 for details). On the basis of the total geological offset, there are five normal faults (F1-5) and two  
230 thrust faults (F6-7). The two detachments are located between the asthenosphere and crust (DET) and  
231 between the lower and upper crust (DAT).

### 232 2.2.2 Model preprocessing

233 The preprocessing consists in building the model mesh, taking into account the discontinuities, and  
234 establishing the material parameters as well as the boundary conditions. The 2D mesh covers the entire  
235 geological section (Figure 5) with 7492 four-node quadrilateral elements and 7711 nodes. The shape,  
236 number, and size of the mesh elements vary according to the model stratigraphy and discontinuities (faults  
237 and detachments). More specifically, the mesh element size is  $\sim 0.5 \text{ km}^2$  near the fault planes,  $\sim 1 \text{ km}^2$  at  
238 the free surface, and reaches a maximum area of  $\sim 2 \text{ km}^2$  toward the model edges.

239 The boundary conditions include the gravity force and basal shear tractions. They have been  
240 applied in two load cases. The first one includes gravity only. The force is applied gradually, and the model  
241 is stabilized under the gravity. The second load case includes gravity and the basal shear tractions oriented  
242 toward the right-hand side. The gravity is inherited by the first load case, and the model is thus pre-stressed

243 at the beginning of the second load case, where the basal tractions are activated gradually. The gradual  
244 activation of the boundary conditions over a few iterations improves the stability of the model without  
245 introducing fictitious oscillations within the model. The improvement is significant in the early evolution of  
246 the model and less apparent later. As in Hetland and Hager (2006), our model reaches a mature state but in  
247 a shorter time. The basal shear tractions represent the mantle convection in the Tyrrhenian asthenosphere  
248 and the Adriatic slab rollback. These conditions are necessary to explain the present-day contraction-  
249 extension pair across the Apennines (e.g., Doglioni et al., 1991; Doglioni et al., 1999; Rosenbaum and Lister,  
250 2004; Doglioni et al., 2007; Barba et al., 2008, Carafa and Bird, 2016). Both conditions are simulated by  
251 north-eastward basal tractions and velocities, represented by horizontal vectors at the base of the model  
252 (Figure 5). The model bottom edge is thus allowed to move freely in the horizontal direction and is locked  
253 in the vertical direction while both sides are locked along the horizontal direction and free along the  
254 vertical direction.

255 The length of the model and the boundary conditions were imposed by verifying that tension and  
256 compression could coexist within the section and by taking into account that the transition between  
257 tension and compression can occur in different places depending on the material resistance to deformation  
258 and the basal shear traction. The model deformation is simulated using elasto-visco-plastic rheology:  
259 elastoplasticity from 0 km to 25 km depth for the upper and intermediate crust, and viscoplasticity from 25  
260 km to 40 km depth (Figure 2) to reproduce the behaviour of the lid, asthenosphere, and lower crust. The  
261 viscoplastic rheology is controlled by the following equation (as implemented in our finite element  
262 software)

$$\dot{\epsilon} = A\sigma^m \epsilon \quad (1)$$

266 where  $\dot{\epsilon}$  and  $\epsilon$  are the equivalent creep strain rate and creep strain, respectively;  $A$  is a constant;  $\sigma$  is the  
267 stress, and  $m$  is the stress exponent (Table 2). For stress values greater than the yield stress, the layers S5  
268 to S7 behave plastically and the model produce plastic deformation patterns at depth as in Ellis and  
269 Stockhert (2004).

270 The seven faults and two detachments (Table 1) were modelled by duplicating the mesh nodes on  
271 both sides of the discontinuities (Melosh and Raefsky, 1981) so that their displacement can be introduced  
272 into the continuum problem without altering its dimensionality.

### 273 **2.2.3 Model optimization through interseismic deformation**

274 The model optimization consists in thoroughly exploring the variability of all features and  
275 parameters within physically possible ranges, in comparing the model horizontal velocity at the free surface  
276 with the reference geodetic velocity, and then validating the model using a parametric analysis.

277 We adopted a trial-and-error approach and used the RMS deviation as a measure to ranking the  
278 performance of each model realization. The natural variability of model parameters and lack of knowledge  
279 about some model features are taken from the pertinent literature on numerical models and geophysical  
280 investigations performed in the study area. The various model realizations incorporate variations of the  
281 geometry, rheological parameters, boundary conditions, and discontinuities (faults and detachments). The  
282 variability ranges are detailed below, and values are listed in Tables 1 and 2.

283 As regards the model geometry, the outline and thickness for each layer were varied in a range of  
284 approximately 5 km; the ITAM was positioned at various depths between 25 and 40 km (see Figure 2). To  
285 control the effect of the boundary conditions, we varied the model length on both sides, up to a total  
286 length of 250 km, and its thickness up to 50 km. Also, to accommodate the relative motions between the  
287 surface plate velocities from GPS data and the convecting mantle, we used a range of basal shear traction  
288 varying from 1 to 10 MPa and roll-back velocity ranging from 0 to 2 mm/yr. About the discontinuities, the  
289 fault geological kinematics was used for guiding the choice of some fault parameters, but it was not  
290 imposed in the model realizations. All faults were unlocked for various widths and exploring all  
291 combinations of locked and unlocked faults. Also, for the detachments, we examined various unlocking  
292 lengths and depth positions according to the geometry of relevant model layers (rightmost column of Table  
293 1). We also varied the rheological parameters as described in Table 2. Mainly, we adopted low viscosity  
294 values for the asthenosphere (Tyrrhenian side) and high viscosity values for the lid and lower crust (Adriatic  
295 side).

296 An exhaustive exploration of all parameter ranges described above through reasonably small  
297 discrete steps would require a massive number of over 10 million possible combinations. However, not all  
298 combinations would necessarily be mutually exclusive, and a few preliminary tests revealed that many of  
299 them would produce very high RMS deviations. We thus performed approximately 3,000 model realizations  
300 and chose the realization that yielded the least RMS deviation as the best candidate model. We then  
301 validated this model choice by performing a parametric analysis of all model parameters, and verified if a  
302 small parameter alteration increases the RMS deviation significantly with respect to the best candidate  
303 model. Since the reference geodetic velocity represents the interseismic period, the best candidate model  
304 was then adopted as the best interseismic reference model.

### 305 **2.3 Slip rate determination**

306 The slip rate distribution at depth is obtained by using the best interseismic reference model while  
307 letting the faults slip to simulate the long-term behaviour. Similarly to Barba et al. (2013) and Finocchio et  
308 al. (2013), we adopted a simplified formulation and applied zero friction to the fault interface. Although  
309 usually small, the friction is never zero on a fault plane. Nonetheless, friction mostly controls the early  
310 stages of fault development, and the behaviour of hosting rocks in the near-fault region as evident from

311 thickened layers, kinks, and drag folds in geological sections. In our case, the faults are all mature geological  
312 structures (generally formed in post-Miocene time but deemed to be still active in the Late Pleistocene -  
313 Holocene). In addition, the term of comparison for their recent activity is the horizontal geodetic velocity  
314 from very sparse GPS stations whose average distance from one another is larger than the projection to the  
315 ground surface of fault plane-widths (cf. Figure 1 and Figure 3a). This suggests that the effects of a non-zero  
316 friction would hardly be detected by the model. In all cases, with this approximation our slip rate estimates  
317 shall represent an upper limit.

318         Except for the fault locking status, everything else is left unchanged. We adopt a simulation time of  
319 10 kyr. This duration is chosen to be long enough for the slip rate determination to be compared with the  
320 order of magnitude of geologically-derived slip rates, and it is also short enough for the model properties  
321 not to incur substantial changes. For example, the width of the simulated faults does not have to increase  
322 to reproduce the fault growth through propagation. We thus assume that the model properties and driving  
323 forces remain constant for the 10-kyr-long simulation time and the system is not affected by the fault slip.  
324 For each unlocked fault node, the total slip at the end of each model realization is divided by the simulation  
325 time. However, not all faults are included in every model realization. Based on considerations of their  
326 likelihood of being both active and seismogenic (Budnitz et al., 1997, Vol. 1, §4.3; Basili et al., 2013), we  
327 included F2, F3, and F7 in all realizations and alternated the remaining others in various combinations. With  
328 these constraints, we obtained 16 different fault sets. We finally estimate the uncertainty of the slip rate  
329 depth distribution by determining the maximum deviation of the slip rate within the five models with the  
330 least RMS deviation (less than 0.1 mm/yr).

## 331 **3 Results**

332         Our main results are represented by (1) an interseismic deformation model and (2) a fault long-  
333 term slip-rate model. In 1) the simulation time equals the geodetic observation time and all parameter  
334 ranges were explored; in 2) the simulation time is 10 kyr, the parameter were those of the best interseismic  
335 model obtained in 1), and only the discontinuities vary in terms of both presence and locking.

### 336 **3.1 Interseismic model**

337         The best interseismic model, i.e., the model whose velocity distribution at the free surface best fits  
338 the reference geodetic velocity, was obtained by randomly exploring the space of model parameters and  
339 calculating the RMS deviation. Table 3 summarizes the best values for each model parameter. Parametric  
340 analysis was then used to address the robustness of the best model by verifying that the RMS deviation  
341 does not further decrease by altering the best parameter values by a given amount. The results of the  
342 parametric analysis are listed in Tables 4, 5, and 6 (based on RMS in the rightmost column) and best model

343 values are those in Table 3 (see also Figures A1, A2, A3, and A4 in the Parametric Analysis Section of the  
344 supplementary document).

345 Figure 6 shows the horizontal velocity predicted by the best interseismic model compared with the  
346 geodetic filtered velocity. The modelled velocity has only small fluctuations around the reference velocity,  
347 yet always within the confidence intervals, and the most significant deviation is localized at around 150 km  
348 along the section. The overall difference is thus irrelevant and quantified by an RMS deviation of 0.07  
349 mm/yr.

350 The structural architecture of the best model includes the seven layers (S1-S7) shown in Figure 2.  
351 We found in particular that S3 behaves elastically because the data are not sensitive to yield stress values  
352 larger than 0.3 GPa and the Young's modulus in S3 is higher than those in the surrounding layers. We also  
353 found that eastward-oriented forces, applied at the base of the model in the form of shear traction and  
354 velocity conditions, are necessary. Shear traction applied in correspondence with the asthenosphere and lid  
355 took the values of 6.0 MPa and 4.5 MPa, respectively. The eastward velocity applied to the slab had to be  
356 0.55 mm/yr. All of the faults appeared to be fully locked except for F2, which has to be unlocked for its  
357 lowermost width of 10 km. Note that F2 is the fault that generated the M 6.9, Avezzano earthquake in  
358 1915. A good fit of the velocity distribution also requires the presence of an 85-km-long detachment at the  
359 top of the asthenosphere (Table 6). Figure A5 in the Strain Plots Section of the supplementary document  
360 shows the total strain and plastic strain of the best interseismic model.

### 361 3.2 Long-term slip rate model

362 The slip rate was calculated for each fault in 16 possible combinations of fault existence. The  
363 average slip rate at depth for the 16 fault combinations is shown in Figure 7a and Table 7.

364 In particular, for each slip rate depth distribution, Table 7 lists the maximum and average values. To  
365 better appreciate the depth distribution Table 7 also show an asymmetry ratio  $f$  given by  
366

$$367 \quad f = \frac{Z_x - Z_t}{Z_b - Z_t} \quad (2)$$

368  
369 where  $Z_x$  is the depth of the maximum slip rate value on the fault, and  $Z_t$  and  $Z_b$  are the depths of the top  
370 and bottom edge of the fault, respectively. The ratio  $f$  tends to 0 when the maximum slip rate is near the  
371 top edge, tends to 1 when the maximum slip rate is near the bottom edge, and tends to be equal or close  
372 to 0.5 when the maximum slip rate is the middle of the fault.

373 F3, F5, and F6 show  $f$ -values in the range 0.6-1.0, meaning that the maximum slip rate is  
374 systematically located in the lower third of the fault. F7 has the maximum slip rate confined in the upper  
375 half except for the SR13 combination ( $f=0.7$ ). In F1, F2, and F4 the maximum slip rate is mostly located near  
376 the top of the fault.

377 Depending on which fault configuration is chosen, the slip rate can be significantly different for  
378 each different fault. The range of slip rate depth average for each fault varies up to a maximum of ~2.5  
379 mm/yr with an overall average slip rate of approximately 1.1 mm/yr for normal faults and 0.2 mm/yr for  
380 thrust faults.

381 Recalling that the fault kinematics is not imposed in the model, we found that most of the faults  
382 maintain the same sense of movement in any of the 16 combinations, except for F4 and F7 that behave like  
383 a normal or reverse fault depending on which fault combination they are included in. In particular, F4 acts  
384 as a thrust fault only when it is in the same fault combination with F5. Despite having a total geological  
385 offset of reverse type, F6 works in all combinations like a normal fault. In a few combinations, F4 and F7  
386 also show an inverted sense of movement with respect to their total geological offset. The implications of  
387 these results will be discussed later, while the results for all 16 combinations are listed in Table A1 in the  
388 Slip Rates Section of the supplementary document.

389 Figure 7 show the results for SR01 (which includes F2, F3, F4, and F7) which we selected as our  
390 preferred fault combination (see Table 7 for numeric values) and Figure A6 (in the Strain Plots Section of  
391 the supplementary document) shows the total strain and plastic strain. In SR01, F4 has a rather uniform slip  
392 rate depth distribution. F2, instead, has a rather uniform slip rate distribution only in its shallower half  
393 whereas below 6 km depth the slip rate gradually decreases until it becomes one-fourth lower than the slip  
394 rate at the free surface. Conversely, the slip rate varies significantly with depth for F7 and F3. F7 has a slip  
395 rate peak at approximately 5 km depth, close to the fault top. F3 has a maximum slip rate near the bottom,  
396 at about 13-14 km depth, and the maximum slip rate at depth is three times higher than its slip rate at the  
397 free surface.

398 The slip rate uncertainty has small variations with depth, although the uncertainty range is not  
399 symmetric on the mean value (Figure 7b). F7 and F4 have the largest maximum uncertainty ranges,  
400 reaching approximately 0.3 mm/yr and 0.5 mm/yr, respectively. The uncertainty of the average slip rate for  
401 F2, F3, F4, and F7 is 2%, 7%, 20%, and 40%, respectively.

## 402 **4 Discussion**

403 In this work, we have explored the use of finite-element models to calculate the distribution of slip  
404 rate at seismogenic depth for several faults at once. An important aspect of our approach is that faults are  
405 let free to slip under the drive of tectonic forces regardless of their geologically-determined offset. In this  
406 way, any fault in the model is just seen as a crustal discontinuity and its behaviour only reflects the amount  
407 of slip that is necessary for the movement of the model free surface to keep the pace of the independently-  
408 measured geodetic velocity. Our case study is set in the central Apennines, Italy, where normal and reverse  
409 faults coexist at a short distance from one another. Our results are represented by 1) an interseismic  
410 deformation model that provides insights into the geological structure and fault locking; and 2) a long-term

411 fault slip rate model that provides insights on how the slip rate is distributed at depth while the on-fault  
412 and off-fault overall deformation is partitioned among the various model features.

#### 413 **4.1 Interseismic model**

414 The interseismic deformation model was chosen as the model with the best performance among  
415 several thousand trials in reproducing the reference geodetic velocity under the assumption of fault  
416 locking. The main limitation of this approach is represented by the unavailability of GPS data in the offshore  
417 part of the model. Knowing that a few tectonic indicators (e.g. major faults, earthquake focal mechanisms)  
418 suggest the presence of a compressional state of stress in this region, we assumed that the horizontal  
419 velocity tapers to zero in the Adriatic Sea (30 km outside the model section) and, therefore, the modelled  
420 horizontal velocity (Figure 6) was not constrained by the data. Therefore, potentially existing faults in the  
421 offshore region cannot be studied with this particular modelling approach. However, the model is well  
422 constrained by both geodetic and stress data in the Apennine interiors where the best interseismic model  
423 indicates that F2 is unlocked. Therefore, the model suggests that the actual strain conditions in that area  
424 are still affected by postseismic relaxation that follows the M 6.9, Avezzano earthquake of 1915. The  
425 postseismic relaxation is known to last tens of years (Pollitz et al., 2006) and the postseismic effects of the  
426 Avezzano earthquake were already revealed by the analysis of elevation changes occurred over 85 years at  
427 a distance of about 25 km from the F2 surface trace (Amoruso et al., 2005). However, even in regions  
428 where the data are of high quality, the GPS data are not sensitive to fault unlocked sections shorter than 10  
429 kilometres. Thence, the locking width we have found in the interseismic model cannot be used in  
430 applications such as the short-term seismic hazard estimates unless additional considerations about fault  
431 behaviour are made.

432 The interseismic deformation model also provides insights into the geological layering and the  
433 geodynamic context of the area. The southwestern part of the section, i.e. to the southwest of all the  
434 faults, is characterized by the presence of a rigid layer (S3; Figure 2). This layer corresponds to a structural  
435 high made of Triassic dolomites (Di Luzio et al., 2009) that are also known for the seismic and magnetic  
436 properties (Chiarabba et al., 2010; Speranza and Minelli, 2014). Our model confirms the presence of this  
437 layer because either decreasing its rigidity or increasing its plasticity causes a significant lack of fit with the  
438 reference geodetic velocity. We also found a better fit (smaller RMS deviation) when a thinner Tyrrhenian  
439 crust is used, and the ITAM is located in a position more similar to that proposed by Doglioni et al. (1991) or  
440 Di Stefano et al. (2009) and closer to the westernmost position of those suggested by Di Luzio et al. (2009).  
441 From the geodynamic viewpoint, the model indicates that an asthenospheric shear on the Tyrrhenian side  
442 and a slab rollback on the Adriatic side are required, in agreement with Barba et al. (2008, and references  
443 therein) to significantly minimizing the RMS deviation. These boundary conditions thus affect the state of

444 stress and strain within the crust and, together with the other structural and kinematic features control the  
445 transition from the extensional to the contractional domain, and ultimately determine the fault kinematics.

## 446 4.2 Long-term slip rate model

447 Estimating the behaviour of faults on a longer term than that of the interseismic period is not only  
448 useful for improving our understanding of the geodynamic and paleoseismic history of an area, but also for  
449 practical applications, such as the seismic hazard assessment, especially if performed with a probabilistic  
450 approach. The time simulated by the long-term slip-rate model, 10 kyr, is much longer than the GPS  
451 observation time. Therefore, this model setup neither simulate variations in the state of stress or model  
452 driving forces nor predict processes that occur on a time scale of  $10^5$ - $10^6$  years, such as fault growth and  
453 propagation, or the waning or waxing of fault activity. In our model, however, the fault slip is determined as  
454 a consequence of off-fault strain, and this implies that improving the knowledge of rock rheological  
455 properties or subsurface stratigraphy will improve accuracy and robustness of the model slip rate. Our  
456 method, therefore, represents an independent and complementary strategy with respect to geologic slip  
457 rate estimates that depend upon the quality and number of on-fault field observations (e.g., Pantosti et al.,  
458 1996) or to numerical estimates from retrodeformed geological sections, which depend on the quality of  
459 geophysical data and are usually representative of long time intervals (e.g., Maesano et al., 2013). As such,  
460 our method is also a tool to compensate the possible deficit of geologic knowledge on specific active faults.  
461 Since vertical 2D models can easily include gravity, stratification, and traction, our modelling approach is  
462 also complementary to horizontal 2D models that provide the slip rate distribution along the fault trace  
463 (e.g., Bird, 2009; Cowie et al., 2012).

464 The 2D approach, however, has inherent limitations, one of which is the possible out-of-plane  
465 motion, i.e. motion in the direction perpendicular to the model section. On the one hand, this problem can  
466 be solved by 3D models and their use represents a necessary course of action for future work. On the other  
467 hand, in the particular case of our model, the 2D section is not only parallel to the main stress direction, but  
468 it is also perpendicular to the strike of main faults. Therefore, our slip rate estimates represent well the dip-  
469 slip component of the slip rate. We also notice that earthquake focal mechanisms in this region (Figure 3a)  
470 have a very small strike-slip component. We are thus confident that while the overall interseismic out-of-  
471 plane motion is certainly significant as also shown by the normal-to-section component of the GPS  
472 horizontal velocity (Figure 3a), the strike-slip component of slip rate should be limited if not negligible.

473 The slip rate values obtained from our models are rather different from those available in the  
474 literature and obtained through various approaches (Figure 7). Having adopted the zero-friction  
475 assumption one would expect our slip rate to systematically overestimate, though by small amount, the  
476 geological slip rate. We found a rather different situation, described below, which requires a case-by-case  
477 explanation of the possible reasons of the discrepancies.

478 With regard to normal faults (F1-5), our slip rate values are generally higher than those so far  
479 proposed by interpreting on-fault shallow geological data. Apart from a few exceptions, most normal fault  
480 slip rates based on geological point data rarely exceed 1 mm/yr (Galadini and Galli, 2000; Papanikolaou et  
481 al., 2005; Pace et al., 2006; Akinci et al., 2009). Indeed, our model shows that only F3 has average slip rate  
482 values smaller than 1 mm/yr in all fault combinations except one. F1 and F4 are slower than 1 mm/yr only  
483 in a few fault combinations, with F4 sometimes showing an inverted sense of movement with respect to  
484 the total geological offset. F2 and F5 are always faster than 1 mm/yr. The two fault combinations that  
485 include all five normal faults (SR12 and SR16) require that F5 has an inverted sense of movement. In our  
486 preferred fault combination, only F3 has a mean slip rate lower than 1 mm/yr. We tentatively explain these  
487 systematic results in either of two ways on the basis of how most on-fault slip rates for normal faults in the  
488 central Apennines are estimated: 1) they are based on very shallow-depth (few metres for paleoseismic  
489 data) or ground-surface displacement that only capture a portion of the total slip rate and thus represent a  
490 lower limit; 2) they are derived from point data acquired on closely spaced, sub-parallel fault strands that  
491 may represent splays of the same master fault at depth. Conversely, with regard to thrust faults (F6-7), our  
492 slip rate values are systematically lower than those proposed by interpreting subsurface data. In particular,  
493 F6 seems to have reversed its sense of movement. The thrust faults incorporated in our models are actually  
494 those located just to the east of the extension-contraction transition and at the southern end of the central  
495 Apennines fold-and-thrust wedge, whereas most of the thrust faults for which the slip rates were  
496 previously estimated are located in a more central and external position of the central Apennines fold-and-  
497 thrust wedge, on the Adriatic coast or offshore. In addition, most of these thrust-fault slip rates refer to  
498 geological markers that span a much longer time window (~0.1-5.0 My; Vannoli et al., 2004; Bigi et al.,  
499 2013; Maesano et al., 2013) than that of our model. We can explain this slip rate discrepancy with the help  
500 of our preferred fault combination. F6 can be currently (last 10 kyr) involved in the extensional domain and  
501 F7 can be experiencing a phase of relative quiescence with respect to a faster, longer-term average rate.  
502 Alternatively, as sometimes observed for other faults of the fold-and-thrust wedge (Maesano and  
503 D'Ambrogio 2015; Maesano et al., 2015), F7 could be in its late waning stage before deactivation,  
504 considering that the inception age of F7 is rather old (likely Messinian) and thrust faults in the central  
505 Apennines have an average lifespan of approximately 5 My (Basili and Barba, 2007).

### 506 **4.3 Uncertainties and seismic hazard implications**

507 The uncertainty of model parameters could not be formally propagated throughout the simulation  
508 procedure onto the slip rate estimates because not all sources of uncertainties and their amount were  
509 known and the formal propagation of errors of uncertain origin could have become deceptive. As a safe  
510 measure, we have then chosen to adopt the variability arising from model realizations with RMS deviation  
511 smaller than 0.1 mm/yr as the possible variability affecting our fault slip rate estimates. This choice

512 corresponds to five models (Table 4, models EP04, EP07, EP09, EP11, and EP26) with equally significant slip  
513 rates. Such slip rate estimates (see Figure 7) thus incorporate a quantification of the epistemic uncertainty  
514 related to the level of knowledge of faults that is of primary interest, especially in seismic hazard  
515 applications. However, to address which fault set is more reliable than others requires that additional  
516 research and a critical review of the data be carried out on these faults. The choice of the fault set is  
517 beyond the scope of this work, and we have thus provided the information on the model slip rates for all  
518 fault sets in the Slip Rates Section of the supplementary document.

519 Knowledge of slip rate at depth is important because its variations affect earthquake depth  
520 distributions (Nadeau et al., 1999). We have shown that the slip rate at seismogenic depth, as predicted by  
521 physically plausible modelling, can take different shapes even when the faults are close to each other and  
522 presumably controlled by similar tectonic conditions. This consideration implies that also the earthquake  
523 depth distribution may vary significantly for faults located at short distance from one another. Additional  
524 implications can then be devised if slip rate depth distributions, as opposed to slip rate depth averages, are  
525 used to derive the earthquake rates in applications such as probabilistic seismic hazard analysis. Assuming  
526 that the cumulative long-term slip rate results from the sum of an unspecified number of fault slip events,  
527 the probability of future fault slip events is higher where slip rate is higher and vice versa. Therefore,  
528 provided that slip rates are properly used to equate tectonic/geodetic moment rates to seismic moment  
529 rates, the slip rate variation with depth and its uncertainties could severely affect the predicted ground  
530 shaking because of the consequent upward or downward shift of earthquake occurrences. In our preferred  
531 fault combination, for example, F2 would likely be relatively more earthquake-productive than F3 at a  
532 shallow depth and thus be more hazardous than expected from using its depth-averaged slip rate. These  
533 considerations, however, will strongly depend on the strategy adopted in estimating the ground shaking.  
534 For example, the use of a ground-motion prediction equation that uses the Joyner-Boore fault-to-site  
535 distance metric would be totally ineffective in reflecting the slip rate depth distribution for the near-fault  
536 shaking.

## 537 **5 Conclusions**

538 We modelled the crustal deformation that fits the geodetic surface horizontal velocity along a SW-  
539 NE profile in central Italy by taking into account: 1) westward-directed shear basal traction, 2) slab roll-  
540 back, 3) presence of a detachment in the Tyrrhenian side, 3) presence of seven major crustal faults (F1-7).  
541 Our main results are represented by an interseismic model and a long-term slip-rate model.

542 In the interseismic stage, although the majority of the faults appear to be fully locked, F2 (i.e. the  
543 fault that generated the Avezzano, M 6.9 earthquake in 1915) appears to be mostly unlocked. This  
544 observation is consistent with the higher gradient of GPS velocities across this fault zone and could  
545 represent a late stage of the fault post-seismic activity. The average long-term slip rate at depth is

546 approximately 1.1 mm/yr for normal faults and 0.2 mm/yr for thrust faults. Concerning previous slip rate  
547 estimates, most of which derive from the interpretation of surface or very shallow geologic data, our slip  
548 rate values are systematically higher for normal faults and lower for thrust faults. Of all investigated faults,  
549 F6 has a peculiar behaviour. It is located at the transition between the extensional and contractional  
550 domains, and its present-day kinematics remains unclear. In all of our model trials, F6 behaves as a normal  
551 fault despite being known to have a total geologic offset of reverse type. This implies that this fault should  
552 have changed its sense of movement in the last 10 kyr. In other words, the NE migration of the extension-  
553 contraction pair could have reached the F6 location in geologically recent times.

554 We maintain that our slip-rate results is a viable representation of the tectonic activity of these  
555 faults at seismogenic depth and that they may exceed the values obtained by observations limited to the  
556 shallowest portion of the crust which is affected by near-surface processes. The reasons why these  
557 discrepancies exist should be the matter of future investigations. Our model slip rates also take different  
558 shapes at depth even where the faults are close to each other. This fact is visible in most of the fault  
559 combinations used in our slip-rate calculations. We thus suggest that the presence of similar or apparently  
560 similar tectonic characteristics across several faults is not a sufficient condition to generate similar  
561 distributions of slip rate at depth. Therefore, the extrapolation at depth of slip-rates that reflect the surface  
562 activity of faults - a commonly adopted strategy in tectonic studies - should be used with more caution.

563 For preparing the way to incorporate our results into probabilistic seismic hazard assessment, we  
564 considered both epistemic and aleatory uncertainties of model parameters. These uncertainties should be  
565 thoughtfully combined with the uncertainties related to the seismic hazard calculations to avoid their over  
566 or under representation and to evaluate the mutual interdependency with other sources of uncertainties.  
567 However, we underline that the uncertainties arising from our model are of the same order of magnitude  
568 of, if not smaller than, the uncertainties associated with classical geological models. Also, the construction  
569 of our model adopts a reproducible procedure that will allow the reduction of uncertainties whenever  
570 further information or data become available.

## 571 **Acknowledgments**

572 The work was supported by Project “Abruzzo” (code: RBAP10ZC8K\_003) funded by the Italian  
573 Ministry of Education, University and Research (MIUR), which is gratefully acknowledged. We thank M. M.  
574 C. Carafa for reviewing an early version of the manuscript. We also thank S. Ellis and J. J. Martínez-Díaz for  
575 their insightful reviews and suggestions that substantially improved the paper.

## 824 **Figure captions**

825 Figure 1. Map of the study area. The modelled faults are labelled by F1-F7. Normal faults: F1, Val Roveto;  
826 F2, Avezzano; F3, L'Aquila-Borbona; F4, Sulmona; F5, Caramanico. Thrust faults: F6, Citeriore deep; F7,  
827 Citeriore shallow. All faults are from DISS 3.2.0 (DISS Working Group, 2015), except for the traces of F1 and  
828 F5, which are from Tozer et al. (2002) and Ghisetti & Vezzani (2002), respectively. A-A' is the trace of the  
829 numerical model. The black dashed line represents the trace of the CROP11 seismic profile from Patacca et  
830 al. (2008). Historical earthquakes (years 1000-2006) are from CPTI11 (Rovida et al., 2011). The L'Aquila  
831 (2009-04-06) and Jabuka (2003-03-29) earthquakes are from Chiarabba et al. (2009) and Herak et al. (2005),  
832 respectively.

833 Figure 2. Stratigraphy (seven layers, S1-S7; see text for description) of the numerical model section (A-A';  
834 see Figure 1 for location) with the embedded discontinuities (red lines), including seven faults (F1-F7) and  
835 two detachments on the Tyrrhenian side (DET) and Adriatic side (DAT). Note that the intersection between  
836 the Adriatic and Tyrrhenian Moho (ITAM) takes several positions between the marked endpoints (black and  
837 red open circles) in the model.

838 Figure 3. (a) Geodetic velocities (blue arrows) along with 1-sigma confidence error regions (blue ellipses)  
839 from Devoti et al. (2011) in central Italy. The rectangular selection region (dashed outline) for the reference  
840 GPS velocities (Figure 4) is shown. The colour shading approximately represents the deformation domains  
841 from the extension (red) to contraction (blue). Earthquake focal mechanisms (1997-2015) are from  
842 Pondrelli et al. (2011) except for those labelled by numbers: 1) Vannoli et al. (2015); 2) Riguzzi et al. (1989);  
843 3-4) quick solutions of recent earthquakes downloaded from the INGV web portal  
844 (<http://cnt.rm.ingv.it/event/6286861> and <http://cnt.rm.ingv.it/event/6288651>, respectively; last accessed  
845 28/12/2015). Hachured red lines represent the main thrust fronts. (b) Schematic geological cross section  
846 (trace marked as F&F in the map) redrawn from Fantoni & Franciosi (2010) showing the west-dipping  
847 Apennines thrusts and the east-dipping Dinarides thrusts. The assumed geodetic zero velocity point (black  
848 arrow) is positioned at the face-off between the two thrust belts.

849 Figure 4. GPS-derived horizontal velocity: point data (diamonds) along with 1-sigma confidence error bars  
850 projected along the model section (A-A' in Figure 3) and filtered longitudinal velocity (thick black line) with  
851 95% confidence interval (thin grey lines). The extent of the extensional, transitional, and contractional  
852 domains are shown (horizontal arrows; the dashed tail indicates indefinite arrow termination).

853 Figure 5. (a) Finite element mesh and boundary conditions. The rollers indicate that the model can be freely  
854 displaced parallel to the edge, whereas it is locked in the orthogonal direction (the edges are also  
855 deformable). The arrows along the lower long edge represent the basal shear traction (single headed) and

856 the slab rollback velocity (two-headed). (b) Close up view of the fault area showing the smaller elements  
857 around the fault planes. Layer and fault labels are the same as in Figure 2. The model section trace (A-A') is  
858 shown in Figure 1.

859 Figure 6. Horizontal velocity distribution along the model section from the best interseismic model (red  
860 line). The location of modelled faults (F1-F7) along the section is indicated (dashed lines). Other symbols are  
861 as in Figure 4.

862 Figure 7. (a) Average slip rate for the 16 fault combinations (see Figure 1 for the location of F1-F7). The bold  
863 dashed line highlights values from the configuration SR01. (b) Slip rate depth distribution for the  
864 configuration SR01 (black dashed lines) with uncertainties (grey-shaded area) derived by combining results  
865 from the five models with RMS deviation less than 0.1 (grey solid lines).

866

867

868

869 Figure 1. Map of the study area. The modelled faults are labelled by F1-F7. Normal faults: F1, Val Roveto;  
 870 F2, Avezzano; F3, L'Aquila-Borbona; F4, Sulmona; F5, Caramanico. Thrust faults: F6, Citeriore deep; F7,  
 871 Citeriore shallow. All faults are from DISS 3.2.0 (DISS Working Group, 2015), except for the traces of F1 and  
 872 F5, which are from Tozer et al. (2002) and Ghisetti & Vezzani (2002), respectively. A-A' is the trace of the  
 873 numerical model. The black dashed line represents the trace of the CROP11 seismic profile from Patacca et  
 874 al. (2008). Historical earthquakes (years 1000-2006) are from CPT11 (Rovida et al., 2011). The L'Aquila  
 875 (2009-04-06) and Jabuka (2003-03-29) earthquakes are from Chiarabba et al. (2009) and Herak et al. (2005),  
 876 respectively.

878

879

880 Figure 2. Stratigraphy (seven layers, S1-S7; see text for description) of the numerical model section (A-A';  
 881 see Figure 1 for location) with the embedded discontinuities (red lines), including seven faults (F1-F7) and  
 882 two detachments on the Tyrrhenian side (DET) and Adriatic side (DAT). Note that the intersection between  
 883 the Adriatic and Tyrrhenian Moho (ITAM) takes several positions between the marked endpoints (black and  
 884 red open circles) in the model.
