10 **Abstract.** Ground-based high resolution observations of downward longwave irradiance (DLI), surface air temperature, water vapour surface partial pressure and column amount, zenith sky infrared (IR) radiance in the atmospheric window, and all-sky camera images are regularly obtained at the Thule High Arctic Atmospheric Observatory (THAAO, 76.5°N, 68.8°W), North-West Greenland. The datasets for the years 2017 and 2018 have been used to assess the performance of different empirical formulas to infer clear sky DLI. An algorithm to identify clear sky observations has been developed, based on value, variability,  
15 and persistence of zenith sky IR radiance. Seventeen different formulas to estimate DLI have been tested against the THAAO dataset, using the originally determined coefficients. The formulas which combine information on total column water vapour and surface air temperature appear to perform better than others, with a mean bias with respect to the measured DLI smaller than 1 W/m<sup>2</sup> and a root mean squared error (RMSE) around 6 W/m<sup>2</sup>. Some formulas, specifically developed for the Arctic, are found to produce poor statistical results; this is attributed partly to limitations in the originally used dataset, which does not  
20 cover a whole year, or is relative to very specific conditions (i.e., the ice sheet). The bias displays a significant improvement when the coefficients of the different formulas are calculated using the THAAO dataset. The presence of two full years of data allows the investigation of the inter-annual variability, and the use of different years for the determination of the coefficients and the evaluation of results. The smallest values of the bias and RMSE reach 0.1 W/m<sup>2</sup> and 5 W/m<sup>2</sup>, respectively. Overall, best results are found for formulas which use both surface parameters and total water vapour column, and have been developed  
25 from global datasets. Conversely, formulas which express the atmospheric emissivity as a linear function of the logarithm of the column integrated water vapour appear to poorly reproduce the observations at THAAO.

## 1 Introduction

The Arctic region is showing the most intense warming of the globe, because of different regional feedback mechanisms often related to the sea ice decline. Both observed and projected warming rates reach a maximum in the autumn and winter seasons  
30 (Bintanja and Krikken, 2016), when the Arctic surface energy budget is dominated by longwave radiation. Indeed, due to the

large seasonal variation of shortwave radiation, the longwave radiation plays a key role in the Arctic, where the annual total Downward Longwave Irradiance (DLI) is usually more than twice as large as the annual downward shortwave irradiance (Curry et al., 1996). Nevertheless, surface longwave irradiance measurements in the Arctic are particularly scarce, and retrievals of surface radiation budget based on satellite data are notoriously problematic at high latitudes (e.g., Kay and  
35 L'Ecuyer, 2013; Di Biagio et al., 2021).

In clear sky conditions, DLI is determined by the atmospheric concentration of the main greenhouse gases (i.e., principally water vapor but also carbon dioxide, methane, and ozone) and by their radiating temperature. Additionally, Gupta (1989) showed that about 86% of surface DLI is originating between 1000 and 900 mb, and 95% between 1000 and 700 mb, indicating that the main contribution to the surface DLI is related to the composition and temperature of the lowest atmospheric layers.  
40 DLI is also strongly affected by the presence of clouds and by their characteristics. Clouds generally induce an increase of surface DLI which is modulated by cloud cover, altitude, phase, water or/and ice concentration, and cloud particle number and size.

Methods to estimate DLI include the use of complex radiative transfer models or semi-empirical formulas based on available local measurements of atmospheric parameters, the former requiring detailed knowledge of the atmospheric vertical structure and composition. However, these are often not available, especially in the Arctic region (Key et al., 1996) where regular  
45 radiosoundings are scarce. Due to these limitations, various semi-empirical formulas have been developed, and some specifically for the Arctic.

Most of the semi-empirical formulas aim at the DLI estimation in clear sky conditions. This is particularly important because the clear sky DLI is needed to quantify the longwave radiative effect of clouds or other atmospheric components on the surface  
50 DLI. Starting from the pioneering work of Ångström (1918), several formulas for clear sky DLI have been developed, mostly to parameterize the clear-sky atmospheric emissivity. These formulas use surface or columnar atmospheric measurements, such as screen-level air temperature (i.e. air temperature at 2 m above ground), or/and water vapour partial pressure and/or integrated water vapour. Few authors have carried out extensive comparisons among the different formulas for clear sky DLI. Flerchinger et al. (2009) tested 13 different formulas to estimate the DLI under clear sky conditions and 4 formulas for all-sky  
55 conditions using data from 21 sites across North America and China. Formetta et al. (2016) evaluated the performance of 10 different formulas using both literature and site optimized coefficients taking into account data from 24 stations across the USA, chosen among the 65 stations of the AmeriFlux Network. More recently Yang et al. (2023) used a long-term hourly database of DLI and meteorological parameters acquired between 2011 and 2022 at 7 stations of the China Baseline Surface Radiation Network, to evaluate the performances of 3 different DLI formulas both in clear and all-sky conditions.  
60 These authors, as well as others, showed that a site-specific calibration of the formulas used for the DLI estimates strongly improves their performances.

Some studies (e.g., Hanesiak et al., 2001; Niemelä et al., 2001; Jin et al., 2006) tested clear sky formulations specifically for Arctic conditions confirming the need to optimize the DLI formulas also in this region.

The main objective of this paper is to investigate the performance of published and site-optimized DLI formulas in the Arctic environment by means of continuous measurements of surface DLI, screen-level temperature, and water vapor partial pressure, as well as integrated water vapor, obtained at the Thule High Arctic Atmospheric Observatory (THAAO; 76.5°N, 68.8°W; <http://www.thuleatmos-it.it/>), in North-Western Greenland. The analysis uses two full years (2017 and 2018) of observations carried out at THAAO.

The paper is organized as follows. Section 2 describes the site and the measurements used in the analysis, while section 3 discusses the methodology used to identify the clear sky periods selected for the analysis. The atmospheric conditions occurring during the two years and the statistical indices used to evaluate the performances of the DLI formulas are discussed in section 4. Section 5 briefly reviews the DLI formulas used in this study and in Section 6 the results of both original (published) and Thule-optimized formulas are discussed. Conclusions are reported in Section 7.

## 2 Site and measurements

This study uses measurements of surface meteorological parameters, downward longwave irradiance, infrared zenith sky brightness temperature (IBT) in the 9.6-11.5  $\mu\text{m}$  spectral range, and integrated water vapour (IWV) carried out at THAAO during 2017 and 2018. The THAAO is located on South Mountain, at 220 m a.s.l., near the Thule Air Base, along the north-western coast of Greenland. The measurements at THAAO are part of a long-term effort dedicated to the investigation of the Arctic climate. Studies on the evolution of the Arctic polar vortex (e.g., di Sarra et al., 2002; Muscari et al., 2007; Di Biagio et al., 2010; Mevi et al., 2018), aerosol/water vapor/albedo feedbacks (Di Biagio et al., 2012), aerosol properties (Becagli et al., 2016, 2019, 2020; Cali Quaglia et al., 2022), surface radiation (Muscari et al., 2014; Cali Quaglia et al., 2022) were carried out based on measurements at THAAO. Additional instruments, whose observations are used in this analysis, were installed in July 2016 and have been operational since then. The roof of the THAAO building has a clear horizon, free of obstacles, and is a good site for high quality radiation measurements.

Pressure, screen-level temperature and relative humidity ( $P$ ,  $T_s$  and  $RH$ ) are measured by means of a Campbell weather station (temperature and humidity through a HC2-S3 probe) installed on the roof of the THAAO building,  $\sim 3$  m above the ground, and are acquired every 10 minutes by means of a datalogger. The water vapor pressure at the surface level ( $e_s$ , in hPa) has been calculated using the values of relative humidity and of the saturation pressure ( $e_{\text{sat}}$ , in hPa) formulas with respect to water and ice following Wagner and Pruß (2002).

DLI and IBT are measured by a ventilated Kipp&Zonen CGR4 pyrgeometer and by a Heitronics KT19.85 II Infrared Radiation Pyrometer, respectively, with their signals recorded every minute using a datalogger.

The pyrgeometer was calibrated by the manufacturer in 2012, and its calibration has been verified by comparison with freshly calibrated pyrgeometers, traceable to the World Infrared Standard Group (WISG; WMO 2014), in 2013, 2016, and 2019. The CGR4 sensitivity was determined down to  $-40^\circ\text{C}$  in order to obtain reliable measurements also at very low temperatures. The expanded uncertainty on DLI measurements is estimated to be  $\pm 5 \text{ W m}^{-2}$  (Meloni et al., 2012).

The KT19.85 pyrometer was modified by the manufacturer to extend the measurement range from  $-50/200^{\circ}\text{C}$  to  $-150/300^{\circ}\text{C}$ . The instrument is calibrated down to  $-100^{\circ}\text{C}$  and has a response linearity which deteriorates between  $-100$  and  $-150^{\circ}\text{C}$ . The IRT is installed on the roof looking at the zenith; air from inside the building is continuously blown on the pyrometer external window to prevent the formation/deposition of ice and snow. Visual inspections and quality data control confirm that this solution is very effective in keeping the pyrometer external window clean. The pyrometer has a FOV of about  $2.6^{\circ}$  and its accuracy is estimated to be  $\pm 0.5\text{ K} + 0.7\%$  of the temperature difference between the instrument body and the observed target (IRP Operational Instructions, 2008). The overall accuracy in the calibrated range is  $\pm 1.5\text{ K}$  for the operational conditions at THAAO.

IWV is retrieved from brightness temperature values measured at seven different frequencies in the K band, between 22 and 31 GHz by an RPG HATPRO-G2 microwave radiometer (i.e. MWR, Rose et al., 2005). IWV is derived from zenith brightness temperature measurements sampled every 2 seconds and averaged over a minute. The expected accuracy (indicated as root mean squared error, RMSE) on IWV is indicated by the manufacturer to be  $\pm 0.2\text{ mm}$  (or  $\text{kg}/\text{m}^2$ ). Thirty-five Vaisala RS92 radiosondes were launched from THAAO in the period July 2016 – February 2017 (23 in summer and 12 in winter). The mean bias and standard deviation between the values of IWV calculated from the radiosoundings and those retrieved by the MWR are  $-0.18\text{ mm}$  and  $0.35\text{ mm}$ , respectively, confirming the good performance of the developed MWR retrieval (Pace et al., 2017).

**Figure 1.** From top to bottom: time series of  $T_s$ ,  $e_s$ , DLI, IBT, and IWV for years 2017 and 2018. Two major data gaps for DLI and IBT at the end of 2017 and in summer 2019 are due to instrumental problems. The red horizontal line in the IBT plot indicates the level of 210 K, that is considered the highest brightness temperature attainable in clear sky conditions (see text).

115

The surface meteorological measurements have been linearly interpolated at the 1 minute acquisition frequency of the pyrgeometer and pyrometer data.

Time series of  $T_s$ ,  $e_s$ , DLI, IBT, IWV are shown in Figure 1. The annual cycle of all parameters is clearly visible. The periods with large high frequency variability of DLI and IBT generally corresponds with presence of clouds. Several spikes of IWV  
120 may be induced by episodes of rain and deposition of water over the MWR radome, which is occasionally not efficiently cleaned by the instrument blower. As will be discussed below, these data have been discarded as part of the clear sky selection procedure.

### 3 Clear sky screening procedure

An important part of this work is the methodology developed to select the clear sky periods to be used as reference to derive  
125 and test the available and new formulas.

The pyrometer data, acquired simultaneously with data from the pyrgeometer, are used for the clear sky detection. The pyrometer signal is chosen because its spectral band is totally contained in the atmospheric window, and its signal is weakly dependent on IWV, but strongly dependent on clouds occurrence. Moreover, due to its narrow field of view, the pyrometer's signal is strongly dependent on the inhomogeneities usually associated with clouds. These characteristics are important for  
130 determining the presence of clouds and allow to determine clear sky conditions throughout the year, during both daytime and nighttime. One limitation of this technique is that the pyrometer, due to the specific geometry, is sensitive only to clouds falling into the instrument field of view, i.e. at the zenith. The adopted algorithm has been developed to circumvent also this limitation, as will be discussed below.

Optically thick clouds produce a significant increase of IBT, which is expected to be clearly discernible; conversely, the IBT  
135 enhancement is smaller for optically thin clouds. All clouds are expected to induce a significant increase of the high frequency signal variability, except for very homogeneous thick clouds. Thus, by selecting appropriate thresholds for IBT, its standard deviation, and posing some requirements on the persistence of the observed IBT with time, it is in principle possible to identify cloud-free conditions.

The procedure developed to determine the clear sky periods is summarized in the flow-chart of figure 2 and is described below.  
140 The analysis is based on 1-minute IBT data. As first step, 15 minute averages of IBT,  $(\overline{IBT})$ , and the corresponding standard deviation ( $\sigma_{IBT}$ ), have been calculated. The time interval of 15 minutes was chosen following Kassianov et al. (2005), who showed that the typical sky decorrelation time for hemispheric instruments like the pyrgeometer is of the order of 15 min. Large values of  $\sigma_{IBT}$  are associated with the presence of clouds. However, stratiform uniform clouds may produce low values of  $\sigma_{IBT}$ , and therefore the screening must take into account also  $\overline{IBT}$ .

145

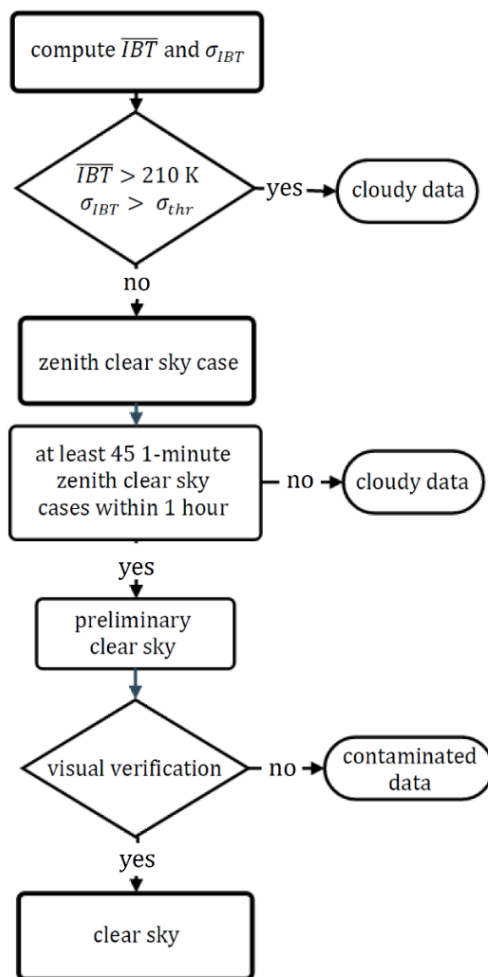

Figure 2. Schematic view of the methodology adopted to identify clear sky conditions (see text).

150 All  $\overline{IBT}$  values  $> 210\text{ K}$  have been considered influenced by clouds, throughout the year (see the red line in the IBT plot of Figure 1). An empirical expression for the threshold values on  $\sigma_{IBT}$ ,  $\sigma_{thr}$ , which varies as a function of IBT, has been derived by looking at pyrometer data and simultaneous sky imager pictures, also taking into account that the signal-to-noise ratio of the pyrometer increases for decreasing IBT. The following expression for the threshold on the standard deviation has been used for IBT between 122.5 and 210 K:

155 
$$\sigma_{thr} = 1 + \frac{10}{[\overline{IBT} - 122.5]^{0.8}} \quad (1)$$

Although the pyrometer sensor is calibrated only above 173 K (-100 °C) and below this brightness temperature it is outside its linearity regime, below 173 K the sensor still responds to changes of zenith sky radiance, and the selection procedure based on  $\sigma_{thr}$  turns out to be applicable.

Temporal intervals characterized by  $\overline{IBT}$  and  $\sigma_{thr}$  lower than the selected thresholds are called zenith clear sky cases (ZCSC),  
160 and are thought to be characterized by clear sky conditions at the zenith over the pyrometer.

The identification of clear sky cases, however, requires that there are no clouds in the sky, and not only at the zenith. Broader  
time intervals, therefore using variability in time as a proxy for spatial variability, have been considered to infer clear sky  
conditions. Each IBT measurement at 1-minute resolution identified as ZCSC has been compared with those obtained in the  
previous and following 30 minutes; the ZCSC measurement has been considered a clear sky period if more than 45 individual  
165 1-minute observations carried out during the 60 minutes interval were classified as ZCSC cases. This second condition is  
intended to identify clear sky conditions for hemispheric instruments like the pyrgeometer.

A visual inspection of the results with respect to the sky imager pictures shows that this methodology is accurate, although it  
may fail in case of formation of snow/ice over the window or dome of the instruments (pyrometer and/or pyrgeometer,  
respectively).

170 The presence of snow/ice induces values of IBT larger than those expected for clear sky, but often  $< 210$  K. At the same time,  
the snow/ice layer may produce a limited time variability of IBT, with  $\sigma_{IBT}$  often below  $\sigma_{thr}$ , and a persistence of IBT values,  
thus satisfying the clear sky selection criteria. In order to remove these cases, all data identified as clear sky have been further  
subjected to a visual inspection, taking advantage of sky imager pictures. The all-sky camera is not ventilated and is more  
subjected to the accumulation of snow/ice than the pyrometer and the pyrgeometer, which are both ventilated. Contaminated  
175 and dubious data, which are however a small fraction of the dataset, are discarded after visual inspection.

## 4 Data and metrics adopted to quantify the goodness of the different formulas

### 4.1 Dataset characteristics

As discussed above, data from 2017 and 2018 have been used in the analysis.

180 Figure 3 shows the distribution of the observed values of  $T_s$ ,  $e_s$ , and IWV, during the two years.  $T_s$  values show a bimodal  
distribution which is related to winter and summer seasons. In particular, 2018 measurements present a lower occurrence of  
intermediate values, resulting in a more pronounced separation of the two seasonal modes. The median value of  $T_s$  is lower  
in 2018 with respect to 2017 (respectively 256.2 and 261.0 K in 2018 and 2017), although a larger occurrence of very low  
temperatures was observed in 2017. Consistently, values of  $e_s < 0.3$  hPa are more frequent in 2017 than in 2018.

Differences between the two years are present also in the occurrences of intermediate values of  $T_s$  and  $e_s$ . The distribution of  
185  $e_s$  values in the two years appears in good agreement with that of IWV retrieved from MWR observations using independent  
information. Data from 2017 show lower extremes of IWV and an intermediate class around 3-5 mm, whereas 2018  
measurements show larger occurrences of IWV in the range of 2-3 mm and between 6 and 7.5 mm. Winter 2017 thus was  
relatively colder and drier than winter 2018 and displayed larger maximum and minimum values.

190 **Figure 3. Annual frequency of occurrence of the measured values of  $\epsilon_s$ , IWV, and  $T_s$  at THAAO in 2017 and 2018.**

The inter-annual differences make the dataset suitable to investigate the applicability of the formulas to somewhat different conditions. As will be discussed below, we will use data from one year to derive coefficients of the different formulas specific for THAAO, and data from the second year to verify the results.

#### 4.2 Statistical indices

Different metrics have been used in the literature to assess the performance of the formulas developed to estimate the atmospheric emissivity ( $\epsilon$ ) or the downward longwave irradiance (DLI). Also the characteristics of the used datasets may differ, depending on the region, season, data averaging interval, and on the source (direct measurements or radiative transfer model outputs). In most cases, measurements are used as reference for the determination of the coefficients appearing in the different formulas, but in some cases radiative transfer calculations have been used instead (e.g., Dillely and O'Brien, 1998). With the aim of providing comparable results between our work and previous studies, a wide set of statistical indices were calculated for the different formulas. The statistical indices were calculated starting from 1 minute averages of clear sky DLI measurements, i.e.  $m_i$ , and from the estimates, i.e.  $p_{i,j}$ , predicted by the different formulas (indicated by the  $j$  index), calculated using the values of  $T_s$ ,  $\epsilon_s$ , IWV concurrent with  $m_i$ . For each formula,  $d_{i,j} = p_{i,j} - m_i$  is defined as the difference between predicted and measured values of clear sky DLI.

The derived indices are the bias, the standard deviation, the root mean square error (RMSE), the skewness, the kurtosis and the 5<sup>th</sup>, 25<sup>th</sup>, 50<sup>th</sup>, 75<sup>th</sup>, and 95<sup>th</sup> percentile of the difference  $d_{i,j}$ , as well as the squared linear Pearson correlation coefficient ( $R^2$ ), and the slope of the of  $p_{i,j} - m_i$  linear fit.

Following Staiger and Matzarakis (2010) and Formetta et al. (2016) also the skill (hereafter named  $T_{skill}$ , Taylor, 2001) and the Kling-Gupta Efficiency (KGE, Gupta, 2009) have been determined to estimate the performance of the examined algorithms. The considered indices are defined as follows:

215

$$bias_j = \frac{1}{n} \sum d_{i,j} \quad (2)$$

$$STD_j = \sqrt{\frac{1}{n-1} \sum_i (d_{i,j} - \bar{d}_j)^2} \quad (3)$$

$$RMSE_j = \sqrt{bias_j^2 + STD_j^2} \quad (4)$$

$$Skewness_j = \frac{1}{n} \sum_i \left( \frac{d_{i,j} - \bar{d}_j}{STD_j} \right)^3 \quad (5)$$

$$Kurtosis_j = \frac{1}{n} \sum_i \left( \frac{d_{i,j} - \bar{d}_j}{STD_j} \right)^4 - 3 \quad (6)$$

220 The values of the kurtosis is an indication of the tail of the distribution: a normal distribution produces a kurtosis equal to 3, higher values are ascribed to a smaller number of large outliers with respect to the normal distribution. KGE includes the effects of correlation, bias, and variability and is expressed as

$$KGE_j = 1 - \sqrt{(r_j - 1)^2 + (a_j - 1)^2 + (b_j - 1)^2} \quad (7)$$

where  $r_j$  is the linear correlation coefficient for formula  $j$ ,  $a_j$  is the ratio between the standard deviations of  $p_{i,j}$  and  $m_i$ , and  $b_j$  is the ratio between the mean values of  $p_{i,j}$  and  $m_i$ .

225 The  $T_{skill}$  index summarize the capability of the different formulas to reproduce the observations and is given by

$$T_{Skill_j} = \frac{4 \cdot (1+r_j)^4}{(s_j+1/s_j)^2 \cdot (1+r_0)^4} \quad (8)$$

where  $r_j$  is the linear correlation coefficient obtained using formula  $j$ ,  $r_0$  is the maximum correlation assumed equal to 1, and  $s_j$  is the ratio between the variances of  $p_{i,j}$  and  $m_i$ .

230 About 100,000 1 minute clear sky DLI measurements were selected and used in the analysis for each of the two years.

## 5 DLI parameterizations

Many algorithms estimating clear sky emissivity or DLI from atmospheric meteorological parameters have been proposed, although only few of them have been tested in the Arctic environment. DLI for clear sky conditions is often expressed as

$$DLI = \varepsilon \sigma T_s^4 \quad (9)$$

235 where  $\varepsilon$  is the clear sky effective emissivity and  $\sigma$  is the Stefan-Boltzmann constant. The clear sky effective emissivity depends on IWV and on other greenhouse gases, and is comprised between a value below 1 (corresponding to a dry atmosphere, with the lower limit determined by the concentration of other greenhouse gases) and 1 for a saturated atmosphere (e.g., Prata, 1996, and references therein).

240 The formulas most commonly used in the literature and the few ones developed and tested for the Arctic region have been selected in this study. The used formulas for  $\varepsilon$  and DLI are summarized in Table 1.

**Table 1.** List of the formulas for the atmospheric emissivity, i.e.  $\varepsilon$ , or the downward longwave irradiance, i.e. DLI, considered in this study, with an ID number identifying each formula. The source region of the data used to derive the coefficients is also indicated.

ID#	Formula	Geographical region	Reference
1	$\varepsilon = 0.7855$	Barrow, Alaska, USA	Maykut and Church, 1973
2	$\varepsilon = 0.67 + 0.05 \cdot e_s^{0.05}$	Tiksi Bay, Jacutzia	Marshunova, 1966
3	$\varepsilon = 9.365 \cdot 10^{-6} \cdot T_s^2$	Northern Australia, Indian Ocean	Swinbank, 1963
4	$\varepsilon = 1 - 0.261 \cdot \exp[-7.77 \cdot 10^{-4} (273 - T_s)^2]$	Various climatic zones	Idso and Jackson, 1969
5	$\varepsilon = 8.733 \cdot 10^{-3} \cdot T_s^{0.788}$	Arctic	Ohmura, 1981
6	$\varepsilon = 1.24 \cdot (e_s/T_s)^{1/7}$	Mid-latitudes	Brutsaert, 1975
7	$\varepsilon = 1.08 \cdot [1 - \exp(-e_s^{Ts/2016})]$	Montana, Alaska, USA	Satterlund, 1979
8	$\varepsilon = 0.70 + 5.95 \cdot 10^{-5} \cdot e_s \cdot \exp(1500/T_s)$	Arizona, USA	Idso, 1981
9	$\varepsilon = 0.0601 + 5.95 \cdot 10^{-5} \cdot e_s \cdot \exp(1500/T_s)$	Arctic/Antarctica	Andreas and Ackley, 1994
10	$\varepsilon = 0.23 + 0.484 \cdot (e_s/T_s)^{1/8}$	Greenland ice sheet	Konzelmann et al., 1994
11	$\varepsilon = [1.2983 - 0.0079 \cdot (T_s - 273.16) + 0.0003 \cdot (T_s - 273.16)^2] \cdot \left(\frac{e_s}{T_s}\right)^{1/7}$	Arctic	Jin et al., 2006
12	$\varepsilon = 1 - (1 + IWV) \cdot \exp[-(1.2 + 3.0 \cdot IWV)^{0.5}]$	Global data and radiation transfer model simulations	Prata, 1996
13 Zhang_A	$DLI = 113.7 + 190.1 \cdot \ln(IWV)$	Barrow, Alaska, USA	Zhang et al., 2001
14 Zhang_B	$DLI = 125.6 + 104.6 \cdot \ln(IWV)$	McGrath, Alaska, USA	Zhang et al., 2001
15	$DLI = 155.12 + 48.75 \cdot \ln(IWV)$	Canadian Arctic	Raddatz et al., 2013
16 Dilley_A	$\varepsilon = [1 - \exp(-1.66 \tau)]$ with $\tau = 2.232 - 1.875 \cdot (T_s/273.16) + 0.7356 \cdot \left(\frac{IWV}{IWV_0}\right)^{0.5}$ , with $IWV_0 = 25 \text{ kg/m}^2$	Global radiation transfer model simulations	Dilley and O'Brien, 1998
17 Dilley_B	$DLI = 59.38 + 113.7 \cdot (T_s/273.16)^6 + 96.96 \cdot \left(\frac{IWV}{IWV_0}\right)^{0.5}$ , with $IWV_0 = 25 \text{ kg/m}^2$	Global radiation transfer model simulations	Dilley and O'Brien, 1998

245

The simplest DLI parameterization is based on the assumption of a constant value for  $\varepsilon$ . Maykut and Church (1973) derived a constant value for  $\varepsilon$  of 0.7855 from 5 years of observations at Barrow (Alaska); this value differs only by 2.7% from the one later proposed by König-Langlo and Augstein (1994) who derived a value of 0.765 using data from Arctic and Antarctic stations. The formulation by Maykut and Church (1973) has been tested (ID# 1).

250

In some cases  $\varepsilon$  has been related with the surface water vapour partial pressure, following the parameterization proposed by Brunt (1932). Marshunova (1966) optimized the coefficients of the formula by Brunt based on monthly mean observations from different Arctic sites, and we used her expression in the analysis (ID# 2).

ID# 3, 4, and 5 are instead based on formulas which use only  $T_s$  to estimate  $\epsilon$ . To justify this approach, Deacon (1970) suggested that, due to the strong coupling between  $T_s$  and IWV, an explicit dependence on humidity may not be necessary.

255 Various formulas (ID# 6-11) use different combinations of  $e_s$  and  $T_s$  to estimate  $\epsilon$ . The coefficients used in the formulas by Satterlund (1979), Andreas and Ackley (1994), Konzelmann et al. (1994), and Jin et al. (2006), corresponding to ID # 7, 9, 10, and 11, respectively, were derived based on Arctic data. Although the formula of Jin et al. (2006) (ID# 11) depends explicitly only on  $e_s$  and  $T_s$ , it takes also into account the temperature and water vapor lapse rates by means of an empirical relationship developed for Arctic sites.

260 More recently, various authors have used IWV to derive  $\epsilon$  or DLI (e.g., ID#12. Prata, 1996; ID# 13 and 14, Zhang et al., 2001; ID#15, Raddatz et al., 2013), while Dilley and O'Brien (1998) developed two different parameterizations (ID#16 and 17) which use IWV and  $T_s$  to derive  $\epsilon$  and DLI. Global radiation transfer simulations were used by Dilley and O'Brien (1998) to determine the coefficients in the formulas.

## 6 Analysis and results

### 265 6.1 Evaluation of the existing formulas

The first objective of this analysis is to employ the observations carried out at the THAAO to evaluate the effectiveness of the 17 selected formulas in the form proposed by the authors (Table1), i.e., using the coefficients they determined.

The mean bias, RMSE, kurtosis, 5<sup>th</sup>, 50<sup>th</sup>, and 95<sup>th</sup> percentiles of the difference  $d_{i,j}$ , KGE and  $T_{skill}$  (see Section 4.2) obtained using 2017 THAAO data are shown in Figure 4. All calculated indices are reported in the Supplementary material, Tables S1 and S2, separately for years 2017 and 2018.

The parameterizations capable of reproducing THAAO data are expected to produce low values of mean bias and RMSE, and large values of kurtosis,  $T_{skill}$  (between 0 and 1), and KGE (between 0 and 1).

KGE presents a larger variability than  $T_{skill}$ , varying from 0.55 (Zhang, A, ID# 13 and Zhang, B, ID# 14) to 0.96 (Prata, ID# 12); on the other hand,  $T_{skill}$  values are all larger than 0.9, with the exception of those obtained with formulas ID# 4, 13, and 14.

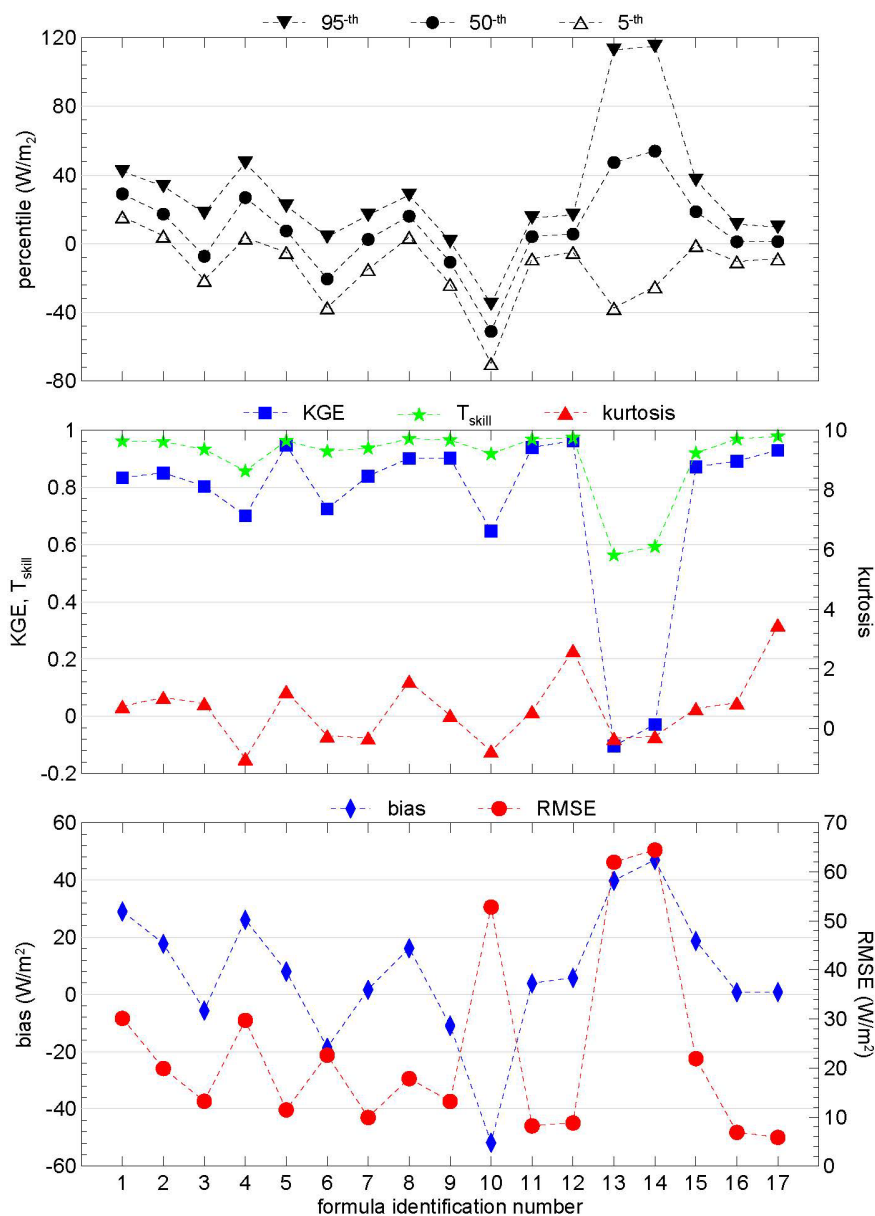

275 The formulas producing the largest values of KGE and  $T_{skill}$  are Jin (ID# 11), Ohmura (ID# 5), Dilley\_B (ID# 17), and Prata (ID# 12); the largest values of the kurtosis are attained by Dilley\_B and Prata.

The best performances in terms of bias and RMSE (absolute value of the bias  $< 6 \text{ W/m}^2$ , and RMSE  $< 10 \text{ W/m}^2$ ) for both 2017 and 2018 are produced by the Dilley\_B, Dilley\_A, Jin, and Prata formulas (respectively ID# 16, 17, 11, and 12 in Figure 4). Thus, good performances are obtained by formulas which express the clear sky emissivity using integrated water vapor and screen-level temperature (Dilley, ID# 16 and 17), IWV only (Prata, ID# 12), screen-level temperature and water vapour content (Jin, ID# 11), and screen-level temperature only (Swinbank, ID# 13).

280 Although the Dilley\_B, Dilley\_A, and Prata formulas (ID# 17, 16, and 12, respectively) and their coefficients were not specifically developed for the Arctic region, they achieve very good results using both IWV and  $T_s$  (Dilley) or only IWV

285 (Prata). These remarkable results suggest that these 3 parametrizations are less affected by the site-specific climatic conditions with respect to the other algorithms.

290 **Figure 4.** Performance parameters of the different formulas for DLI listed in Table 1, tested using 2017 THAAO data: the upper panel shows 95<sup>th</sup>, 50<sup>th</sup>, and 5<sup>th</sup> percentiles (filled triangles, filled circles and empty triangles) of the differences between estimated and measured values of DLI; the middle panel shows KGE (blue squares, left Y-axis),  $T_{skill}$  (green stars, left Y-axis), and kurtosis (red triangles, right Y-axis); the bottom panel displays bias (blue solid diamonds, left Y-axis) and RMSE (red solid circles, right Y-axis). The formula corresponding to the different ID numbers is reported in Table 1.

The parametrization published by Jin (ID# 11) also shows very good performances and the lowest changes in terms of RMSE  
295 between the two years, confirming its effectiveness in the Arctic environmental conditions for which it was developed.

The formulas by Swinbank (ID# 3) and by Ohmura (ID# 5) produce the best results among those using only  $T_s$ .

The low performance displayed by the Zhang's formula, which uses IWV, is probably due to the fact that it has been developed  
using data only from the melting season at Barrow and McGrath, and these data may not be appropriate to reproduce the annual  
changes of DLI in the Arctic. This is partially confirmed by the results of the Raddatz formula (ID# 15), that uses the same  
300 dependence on IWV but obtains a better score.

Although the low performances of Konzelmann's formula was unexpected (ID# 10), since it had been developed and tested  
using measurements carried out on the Greenland Ice Sheet, the different conditions occurring over the ice sheet and at a  
coastal site, such as THAAO, may have played a role.

Small differences in the 2017 versus 2018 values of the indices calculated for each formula are found. Biases and  $T_{skill}$  indices  
305 of the same formula do not show significant differences between the 2017 and 2018 datasets, while RMSE is generally slightly  
smaller and kurtosis larger in 2018. This effect is due to the behaviour of the distribution tails, which are somewhat larger in  
2017, as discussed in section 4.1.

In synthesis, formulas which use IWV and  $T_s$  perform somewhat better than the rest, although significant differences linked  
to the seasonal dependence of the dataset, or to specific conditions or particularly effective parameterizations exist.

310

## 6.2 Determination of THAAO-optimized coefficients

The second objective of this work is to find the coefficients of the considered formulas that best reproduce the THAAO  
datasets. The results are reported in Table 2 for both year 2017 and 2018.

The analytical form of the Zhang\_A (ID# 13), Zhang\_B (ID#14) and Raddatz (ID# 15) formulas is the same, so the results  
315 obtained by optimizing those coefficients are displayed only for formula ID#13. Similarly, formulas ID# 8 and 9 of Table 1  
have the same analytical form, and produce a single fit with respect to the THAAO data (ID# 8). The parametrization of  
Maykut, ID# 1, was implemented using both the annual mean (as the authors do) and the median values of  $\epsilon$ . No significant  
differences in the coefficients and statistical results are found.

Figure 5 shows the performance of the parameterizations for 2017; in this case the same annual dataset has been used to  
320 determine the coefficients appearing in the formulas and the statistical indices discussed in section 4.2. Detailed statistical  
indices for years 2017 and 2018 are reported in the Supplementary material, Tables S3 and S4.

The bias is always smaller than  $1.3 \text{ W/m}^2$ , except for the Konzelmann formula (ID# 10) in both 2017 and 2018 and for the  
Zhang formula in 2018 (ID# 13 and). In general, similar values of the bias are obtained with data from 2017 and 2018, except  
for the Zhang formula, for which a large change of the bias between the two years is found ( $-0.09$  in 2017 and  $-2.01 \text{ W/m}^2$  in  
325 2018).

**Table 2: Formulas from Table 1 with the coefficients determined using the data from THAAO. Data from 2017 and 2018 are used separately. Formulas 8 and 9, and formulas 13, 14 and 15, of Table 1 are equivalent when applied to the THAAO data. The same formula identification numbers of Table 1 have been used also in this Table.**

ID#	Dataset year	Formula	Reference
1	2017 2018	$\varepsilon = 0.6748$ $\varepsilon = 0.6684$	Maykut and Church, 1973
2	2017 2018	$\varepsilon = 0.6177 + 0.05 \cdot e_s^{0.04179}$ $\varepsilon = 0.6182 + 0.05 \cdot e_s^{0.04004}$	Marshunova, 1966
3	2017 2018	$\varepsilon = 9.701 \cdot 10^{-6} \cdot T_s^2$ $\varepsilon = 9.802 \cdot 10^{-6} \cdot T_s^2$	Swinbank, 1963
4	2017 2018	$\varepsilon = 1 - 0.3021 \cdot \exp[2.719 \cdot 10^{-4} (273 - T_s)^2]$ $\varepsilon = 1 - 0.2990 \cdot \exp[3.311 \cdot 10^{-4} (273 - T_s)^2]$	Idso and Jackson, 1969
5	2017 2018	$\varepsilon = 8.367 \cdot 10^{-3} \cdot T_s^{0.788}$ $\varepsilon = 8.351 \cdot 10^{-3} \cdot T_s^{0.788}$	Ohmura, 1981
6	2017 2018	$\varepsilon = 1.3836 \cdot (e_s/T_s)^{1/7}$ $\varepsilon = 1.4127 \cdot (e_s/T_s)^{1/7}$	Brutsaert, 1975
7	2017 2018	$\varepsilon = 1.040 \cdot [1 - \exp(-e_s^{T_s/2830})]$ $\varepsilon = 1.042 \cdot [1 - \exp(-e_s^{T_s/2670})]$	Satterlund, 1979
8	2017 2018	$\varepsilon = 0.6338 + 7.000 \cdot 10^{-5} \cdot e_s \cdot \exp(1500/T_s)$ $\varepsilon = 0.6362 + 6.237 \cdot 10^{-5} \cdot e_s \cdot \exp(1500/T_s)$	Idso, 1981; Andreas and Ackley, 1994
10	2017 2018	$\varepsilon = 0.4345 + 0.4565 \cdot (e_s/T_s)^{1/8}$ $\varepsilon = 0.4414 + 0.4408 \cdot (e_s/T_s)^{1/8}$	Konzelmann et al., 1994
11	2017 2018	$\varepsilon = [1.2953 - 0.008340 \cdot (T_s - 273.16) + 0.000144 \cdot (T_s - 273.16)^2] \cdot \left(\frac{e_s}{T_s}\right)^{1/7}$ $\varepsilon = [1.2970 - 0.009604 \cdot (T_s - 273.16) + 0.000099 \cdot (T_s - 273.16)^2] \cdot \left(\frac{e_s}{T_s}\right)^{1/7}$	Jin et al., 2006
12	2017 2018	$\varepsilon = 1 - (1 + \text{IWV}) \cdot \exp[-(0.6091 + 7.287 \cdot \text{IWV})^{0.3305}]$ $\varepsilon = 1 - (1 + \text{IWV}) \cdot \exp[-(0.5480 + 7.610 \cdot \text{IWV})^{0.3225}]$	Prata, 1996
13	2017 2018	$\text{DLI} = 134.02 + 50.916 \cdot \ln(\text{IWV})$ $\text{DLI} = 128.42 + 51.251 \cdot \ln(\text{IWV})$	Zhang et al., 2001; Raddatz et al., 2013
16 Dilley_A	2017 2018	$\varepsilon = [1 - \exp(-1.66 \tau)]$ with $\tau = 1.4951 - 1.1136 \cdot (T_s/273.16) + 0.7220 \cdot \left(\frac{\text{IWV}}{\text{IWV}_0}\right)^{0.5}$ , and $\text{IWV}_0 = 25 \text{ kg/m}^2$ $\varepsilon = [1 - \exp(-1.66 \tau)]$ with $\tau = 1.4502 - 1.0685 \cdot (T_s/273.16) + 0.7029 \cdot \left(\frac{\text{IWV}}{\text{IWV}_0}\right)^{0.5}$ , and $\text{IWV}_0 = 25 \text{ kg/m}^2$	Dilley and O'Brien, 1998
17 Dilley_B	2017 2018	$\text{DLI} = 52.083 + 112.403 \cdot (T_s/273.16)^6 + 117.532 \cdot \left(\frac{\text{IWV}}{\text{IWV}_0}\right)^{0.5}$ , and $\text{IWV}_0 = 25 \text{ kg/m}^2$ $\text{DLI} = 49.885 + 117.098 \cdot (T_s/273.16)^6 + 109.674 \cdot \left(\frac{\text{IWV}}{\text{IWV}_0}\right)^{0.5}$ , and $\text{IWV}_0 = 25 \text{ kg/m}^2$	Dilley and O'Brien, 1998

The results of the Konzelmann formula (ID# 10) suggest that for the environmental condition of THAAO, the value of the exponent more suitable to express the dependence of  $e_s/T_s$  is  $1/7$ , and not  $1/8$ .

In 2017 values of  $RMSE < 8 \text{ W/m}^2$  are found for the Dilley\_B, Dilley\_A, Prata, Jin, Idso, Satterlund, Ohmura, and Marshunova (ID# 16, 17, 12, 11, 8, 7, 5, and 2, respectively) formulas; for all these cases the bias is  $< 0.25 \text{ W/m}^2$ . The performances of the  
335 Ohmura and Marshunova formulas suggest that, when coefficients are retrieved using the same dataset, good results may be obtained also for formulas which include only dependencies on  $T_s$  or  $e_s$ .

It is interesting to note that the values of RMSE in 2018 are generally lower than in 2017. This is possibly due to the meteorological conditions of 2017, which are characterized by a colder and drier winter and larger spread of the  $T_s$ ,  $e_s$  and IWV values (see Section 4.1).

340 The smallest RMSE values ( $< 5.2 \text{ W/m}^2$  in 2018 and  $< 6.0 \text{ W/m}^2$  in 2017) are attained by the parameterizations which include both the surface and the column information, i.e., the two formulas by Dilley and O'Brien (ID#16 and 17), and the one by Prata (ID# 12), for which the emissivity is a function of IWV.

As occurred using the original parameters, the smallest year-to-year change of RMSE value occurs for the formulas by Jin (ID#11, RMSE of 6.58 and 6.96  $\text{W/m}^2$  respectively in 2017 and 2018), which also present very low values of the bias. The  
345 formula by Jin displays better statistical indices among those which use only surface information.

KGE and  $T_{skill}$  show similar behaviour, with smaller values for the Maykut, Swinbank, Brutsaert, Zhang, and Raddatz (ID# 1, 3, 6, 13,). The poor performance of the formulas by Zhang and Raddatz, also with the optimization of the coefficients, suggests that a formulation of atmospheric emissivity as  $\ln(IWV)$  is not adequate to describe the conditions occurring at THAAO.

As expected, the optimization of the different formulas using data of both 2017 and 2018 produces a substantial improvement  
350 of almost all statistical indices. Generally, the main effect of the optimization of the coefficients for the local conditions is to reduce significantly the value of the bias. A striking difference between the statistical indices calculated with the original coefficients found in the literature and those obtained with coefficients retrieved for the THAAO dataset can be noticed for the percentile distribution in Figures 5 and 6. Also, a general increase of KGE,  $T_{skill}$ , and kurtosis is found.

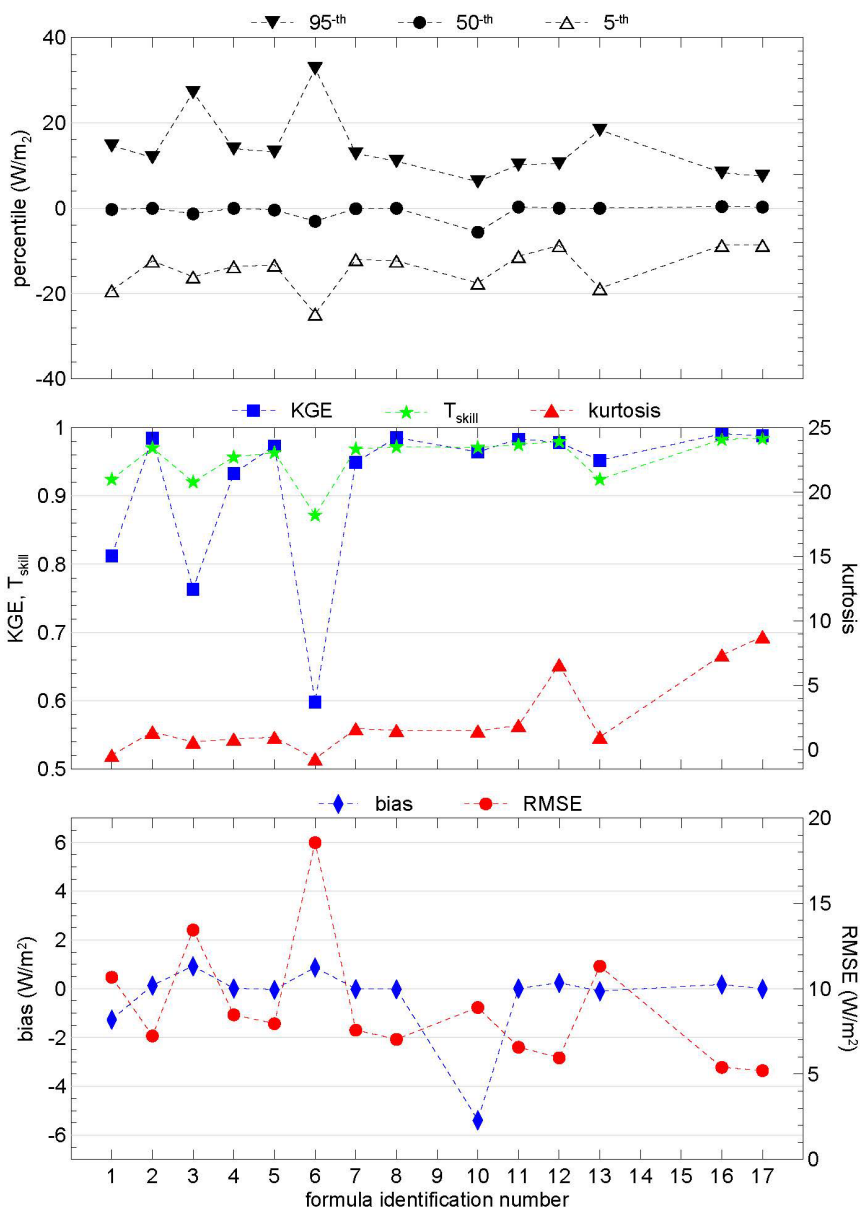

355 To test the representativeness of the formulas with respect to inter-annual variability, statistical indices were calculated using the annual data which were not used to derive the coefficients, i.e., data for 2018 were used for verification of the parametrizations obtained using coefficients derived employing 2017 data, and vice versa.

The main results of this analysis are shown in Figure 6. The full set of statistical indices for the two cases is reported in Tables S5 and S6 of the supplementary material.

360 Lowest values of the bias are produced by the Prata (ID# 12) and Jin (ID# 11) formulas. On the other hand, the best performances in terms of RMSE are obtained with the two formulas by Dilley and O'Brien (ID# 16 and 17). The Dilley\_B formula (ID# 17) produces the smallest RMSE value. This parameterization shows a bias of about  $\pm 1.2 \text{ W/m}^2$ .

The largest inter-annual variability of the bias is shown by the formulas that produce the worst results, and that hence appear less suited for representing the Thule environment.

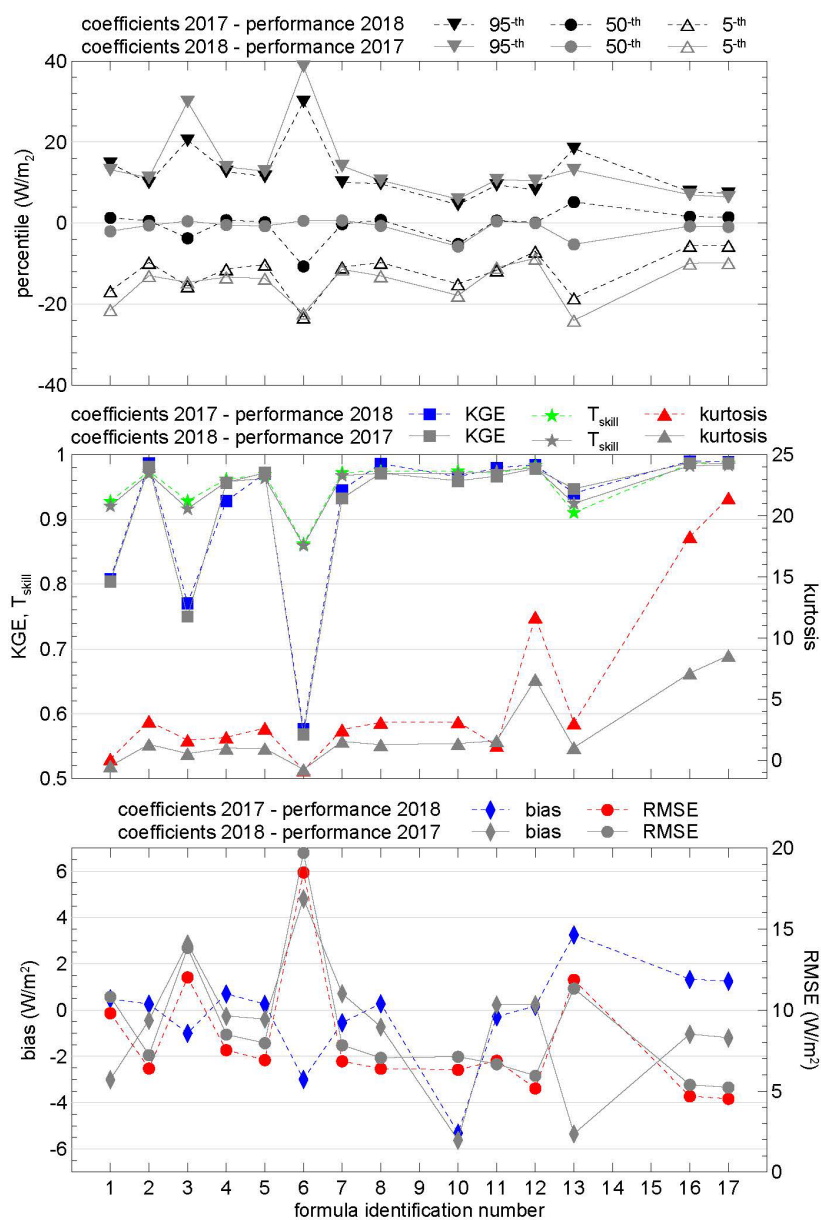

365

**Figure 5.** Same as Figure 4, but the coefficients of the different parametrizations were derived from THAAO 2017 data and tested using the data of the same year. Please, note the change of vertical scales with respect to Figure 4.

The Jin's formula presents a very small bias for both years, and a nearly identical value of RMSE, confirming that it is poorly sensitive to changes of the dataset in the Arctic environment.

370

Testing the parametrization using different years produces changes in the values of the bias, but not in those of RMSE; this suggests that the value of the RMSE is mainly determined by the differences in meteorological conditions. The lower is the standard deviation, the better the parameterization uses the information to reproduce the DLI variability.

375

380

**Figure 6.** Same as Figures 4 and 5, but this time the different parametrizations were optimized using one year of data and tested using the other (i.e., coefficients were determined with 2017 data and tested using 2018, and viceversa). This produces the two data points that are displayed for each formula. Grey symbols and lines are relative to coefficients derived from 2018 data, and performance parameters calculated with 2017 data. Coloured lines and symbols refer to results obtained using coefficients retrieved with 2017 data and performance parameters calculated with 2018 data.

In most cases the values of the KGE and the  $T_{\text{skill}}$  are larger than 0.95. High values of the kurtosis are attained, as also outlined for the previous analysis, by the Dilley\_A, Dilley\_B, and Prata formulas (ID# 16, 17, and 12).

## 385 7 Summary and conclusions

This study investigates the performance of different formulas largely used in the literature to determine the clear sky downward longwave irradiance in the Arctic from meteorological parameters. The existing formulas need to be tuned to the environmental conditions of the application region; the Arctic environment, in particular, poses specific challenges, due to the peculiar regime of temperatures, atmospheric water vapour content, and their vertical distribution.

390 The analysis has been carried out on the basis of high time resolution data collected during 2017 and 2018 at the Thule High Arctic Atmospheric Observatory (THAAO), which is located at 76.5°N, on to the North-Western Greenland coast. Measurements of all relevant parameters used in the existing formulas, including the integrated water vapour, are routinely carried out at THAAO, providing the possibility to test the algorithms.

A clear sky selection method was first developed to remove cloudy data. The cloud screening method is based on measurements of zenith sky brightness temperatures made in the 9.6-11.5  $\mu\text{m}$  spectral window simultaneously to the other observations. Measurements in this spectral interval are poorly dependent on water vapour and very sensitive to clouds. The cloud screening uses a combination of thresholds on the zenith sky brightness temperature, its variability, and the persistence of low infrared brightness temperature values. The results of the clear sky selection have been verified with respect to sky imager pictures, and appears to be reliable and robust.

400 Seventeen different formulas, among those most widely used in the literature, and including those specifically developed for the Arctic, have been chosen to be tested against the THAAO observations. Various statistical parameters have been adopted to assess the performance of the different formulas; these include bias, RMSE, the Kling-Gupta Efficiency, and the Taylor skill.

The analysis was carried out in two separate phases. In the first phase, the formulas with the originally derived coefficients, 405 have been tested against the clear sky THAAO dataset. In the second phase, the coefficients of all the considered formulas were optimized to Thule, by deriving them from the THAAO dataset.

The availability of two full yearly cycles of data gives the possibility to: 1) test the formulas separately over two independent years, investigating the inter-annual variability of the results, and 2) use two different datasets, one for the determination of the coefficients and another for the verification of the performance.

410 The main results of the analysis may be summarized taking into account the performance of the formulas with the original coefficient and those with the optimized coefficient.

Among the original formulas those which determine the atmospheric emissivity in terms of IWV and screen-level temperature, in particular those by Dilley and O'Brien (1998) (ID# 16 and 17), appear to perform better than those which are based on screen level measurements only; in general, best performances of formulas which use original coefficients produce biases  $< 3$  415  $\text{W/m}^2$ , and  $\text{RMSE} < 7 \text{ W/m}^2$ . The formula by Jin et al. (2006) (ID# 11), which was developed on the basis of Arctic data using

screen level data, but that takes into account the temperature and water vapor lapse rates, produces also very good results, and seems to be independent on the annual dataset used.

The optimization of the formulas, i.e., determination of the coefficients based on the THAAO dataset, produces a significant reduction of the bias and improvement of most statistical indices. Various formulas specifically developed for the Arctic appear to produce good results in matching THAAO data. There are however notable exceptions when the formulas have been derived from only a fraction of the year (e.g., Zhang et al., 2001), or over sites with very specific conditions (e.g., over the Greenland ice sheet, Konzelmann et al., 1994). Among all the re-tuned formulas, those which use IWV and screen level data produce better results; the mean bias, estimated with a separate dataset from the one used to determine the coefficients, is  $< 1.33 \text{ W/m}^2$  for the formulas by Dilley and O'Brien (ID#16 and 17), and Prata (ID# 12). The same formulas present the minimum values of RMSE,  $\leq 6 \text{ W/m}^2$ , which are associated with maxima of the kurtosis and high  $T_{\text{skill}}$ .

Considering both the original and optimized formulas in terms of RMSE the parametrization of Dilley and O'Brien (ID#16 and 17), Prata (ID# 12) and Jin (ID# 11) present the best performance on the used datasets. It is worth to note that, expressions by Dilley and O'Brien (ID#16 and 17) and by Prata (ID# 12), which were developed on the basis of global data, appear to perform better at Thule, even with the original coefficients, than formulas specifically developed for Arctic conditions. On the other hand formulas expressing the atmospheric emissivity only as a linear function of  $\ln(\text{IWV})$  appear to produce unsatisfactory results when applied to the THAAO database.

Thus, specialized formulas allow to retrieve the clear sky DLI within about  $5\text{-}7 \text{ W/m}^2$ , as also suggested by the distribution of the percentiles. We intend to use these estimates to derive the IR cloud radiative perturbation, which is calculated as the difference between the measured DLI in cloudy conditions, and the corresponding clear sky DLI; uncertainties on the estimates of clear sky DLI directly influence our capability to determine the cloud radiative perturbation, which is fundamental to assess the role that clouds are playing in the Arctic climate. There is the need to reduce the uncertainties on these determinations, since a relatively large uncertainty on the estimated values of the clear sky DLI impairs our ability to determine the radiative effect of thin and even moderate clouds.
