ABSTRACT

The Sunyaev–Zel’dovich (SZ) effect (Sunyaev et al. 1972) is a signature of the inverse Compton-scattering of cosmic microwave background (CMB) photons by hot electrons in the intervening gas throughout the universe. The effect can be measured at three frequencies by the BOOMERANG 2003 flight, which constrains SZ fluctuations in the 10 arcmin to 1 deg angular range. Propagating errors and potential systematic effects through simulations, we find $\sigma_8^{\text{SZ}} < 1.14$ at the 95% confidence level. When combined with other CMB anisotropy and SZ measurements, we find $\sigma_8^{\text{SZ}} < 0.92$ (95% c.l.).

Subject headings: cosmic microwave background — cosmological parameters — cosmology: observations — large-scale structure of universe

1. INTRODUCTION

The Sunyaev–Zel’dovich (SZ) effect (Sunyaev et al. 1972) is a signature of the inverse Compton-scattering of cosmic microwave background (CMB) photons by hot electrons in the intervening gas throughout the universe. The SZ effect is generally subdivided into two subcomponents: the kinetic effect due to the bulk motion and the thermal effect due to energy transfer from hot electrons. The latter is expected to be the largest modification to the background temperature during photon transit from the last scattering surface. We will concentrate on it hereafter and refer to it as the SZ signal.

The strongest SZ perturbations to the CMB temperature are dominated by scattering of photons via hot electrons in massive galaxy clusters (Komatsu & Kitayama 1999).
negative side to the positive side.

A dataset of the form needed for a study of the large-scale structure SZ effect is provided by the 2003 flight of the balloon-borne BOOMERANG experiment (Masi et al. 2006). This instrument derives directly from the BOOMERANG payload that was flown in 1998 and resulted in first high signal-to-noise maps of the CMB anisotropy with sub-horizon resolution (de Bernardis et al. 2000). The instrument was launched by NASA on 2003 January 6 from Williams Field near McMurdo Station, in Antarctica. The flight lasted a total of 311 hours until 2003 January 21 and 119 hours of this observing period were devoted to scanning a deep survey region. The remaining time was spent on scanning a larger shallow survey and a section of the Galactic plane. Here, we concentrate on a search for SZ effect in the central deep field over 100 deg² with the highest signal-to-noise ratio.

In this Letter, we report the first statistical limits of the SZ signal at sub-degree angular scales at these wavelengths. The discussion is organized as follows: in Section 2 we detail our approach to extract the SZ signal from the multifrequency BOOMERANG dataset; in Section 3 we detail our simulations used to estimate statistical and systematic uncertainties; and in Section 4 we present our results.

2. CMB AND FOREGROUND REMOVAL

To separate the SZ signal from all other sources of anisotropies, we adopted a technique well-known in the literature for removing foregrounds from the CMB anisotropies (Tegmark & Efstathiou 1996; Tegmark et al. 2003; Amblard et al. 2007). In our case, instead of recovering the primordial CMB signal, we recover SZ fluctuations by minimizing the covariance relative to the SZ frequency dependence, and treat primordial fluctuations as another source of noise. In the remainder of this Letter, we will refer to “foregrounds” as all the additional emissions (CMB, Galactic dust, far-IR sources or FIRB, radio point sources) to the SZ effect.

The power spectrum of the SZ can be obtained from a weighted mean of the power spectra at different frequencies:

\[ C_{SZ} = w^T C w \] (Cooray et al. 2000).

The weights \( w \) at each frequency \( i \) and multipole \( \ell \) can be obtained by minimizing the covariance of data multipole moments \( C \equiv \langle \hat{d}_i \hat{d}_j \rangle \) subject to the constraint that SZ estimation is unbiased \((\sum_i w_i = 1)\).

In the case of BOOMERANG maps, each frequency channel consists of several detectors. We distinguish individual detectors with the indices \((\alpha, \beta)\), while \((i, j)\) are indices for the frequency channels. In order to minimize instrumental noise more aggressively, we compute the covariance matrix of the signal by averaging all the combinations of cross-spectra between different detectors and ignoring the auto-spectra of the same detector. The contribution of the correlated noise between two different detectors is taken into account in the simulations and removed as part of a residual contribution to the SZ signal.

We construct the binned covariance matrix in multipole \(\ell \) bin \( b \) as

\[ C_{ij} = \sum_{\ell \in b, m \alpha, \beta} \langle \hat{d}_{\ell m}^{i \alpha} \hat{d}_{\ell m}^{j \beta*} \rangle \frac{s(\nu_i)s(\nu_j)b_{\ell i}^\alpha b_{\ell j}^\beta}{\nu_i/\nu_j} \] with \( \alpha \neq \beta, \) if \( i = j \),

where \( s(\nu_i) \) is the SZ frequency dependence at each of the BOOMERANG frequency bands relative to CMB with \( s(\nu) = 2/(x/2)\coth(x/2) \), \( x = h\nu/kT_{CMB} \approx \nu/56.8\)GHz, and \( b_{\ell i}^\alpha \) is the measured beam window function for the detector \( \alpha \) in channel \( i \). Note that with the definition above, in the RJ limit \( s(\nu) \to 1 \) so that \( C_{SZ}(\nu, \nu') = s(\nu)s(\nu')C_{SZ}^{\alpha, \beta} \) where \( C_{SZ}^{\alpha, \beta} \) is the SZ anisotropy power spectrum in the RJ limit. The covariance matrix \( C_{ij} \) is required to be invertible and positive definite. We numerically check this both in data and simulations. In Figure 1 we show the covariance matrix from data and compare it to simulations described below.

Using the data covariance matrix, the optimal weights for the SZ reconstruction are

\[ w = C^{-1}e \] (eC^{-1}e^{-1}

where \( e \) is a unit vector, \( e_i = 1 \). The BOOMERANG channels consist of eight polarization-sensitive bolometers at 145 GHz, and four spider-web bolometers at each of 245 GHz and 345 GHz channels. We make use of data from all these detectors except two detectors that were known in prior studies to be dominated by detector noise (245X and 345Z) (Masi et al. 2006) and two detectors with a significantly higher noise than the others (145Z2 and 345Y), leaving us with seven detectors at 145, three at 245 and two at 345 GHz.

We use the spectral response of each band as measured in lab with sub-percent accuracy. From these bands we derived the values of \((0.49722, -0.21646, -1.01643)\) for \( s(\nu) \) at 145, 245 and 345 GHz respectively. These bands provide ideal frequency coverage for an SZ study with channels in the SZ decrement, near the null, and the increment, respectively. The measured FWHM of the beams is 11.5, 8.5, and 9.1 arcmin for the 145, 245, and 345 GHz channel, respectively (Jones et al. 2006). These values include a 2.4 arcmin pointing jitter. The beams window functions \( b_{\ell i}^{\alpha} \) are in fact numerically derived from physical optics simulations, combined with a Gaussian pointing jitter.

Similar to prior studies with BOOMERANG data, we produced CMB temperature anisotropy (T) maps using the Italian analysis pipeline (Masi et al. 2006) and the TT power spectra with the MASTER method (Hivon et al. 2002). To remove excess atmospheric noise, we filtered out time-ordered data.

NOTES.—The weights and Raw SZ designate the weight vectors for each multipole bin and the SZ power spectrum respectively with both as measured from data. Except in the case of weights \( w \), the values are tabulated in units of \( \mu K^2 \) for the SZ angular power spectrum \( \ell^2 C_\ell / 2\pi \) at the \( \ell \) end of the frequency spectrum.

\(^{(a)}\) The residuals are the average spectra measured on our SZ-free simulations and represent our bias. The total residual is different from the sum of the partial residuals due to small (<10%) random correlation between components.

\(^{(b)}\) The uncertainties are the dispersion measured with our simulations. The final SZ spectrum values are corrected for the noise and foreground bias with the dispersion error from simulations.

\(^{(c)}\) Assuming the WMAP team’s SZ power spectrum with \( \sigma_8 = 0.95 \), the 2-\sigma upper limit we derived from all SZ data. The calculation for Non-Gaussian (NG) covariance makes use of the same halo model as used for this power spectrum.

in each of the detectors in frequency space below 200 mHz. This results in a damping of power at angular scales above \( 1.2^{\circ} \). The effect of this filter, of the scanning strategy, of the sky coverage, and of the pixelization results in an effective window function. This window function is estimated by projecting signal-only sky simulation into detector time-streams. To do that we used 10 sky simulations of the SZ signal, obtained from White (2003) with different normalizations and initial conditions. These time-streams are then analyzed with our pipeline and the resulting angular power spectrum is compared to the power spectrum of the input sky signal to obtain the window function. The 10 different simulations result in slightly different window functions. The scatter in the window function is included in the final error estimate of the SZ signal.

3. SIMULATIONS

Monte Carlo simulations were used in order to estimate the residual signal from correlated detector noise, primary CMB, and foregrounds that is detected as an SZ signal at the end. In fact, when we minimize the covariance in the data to extract the SZ, the optimal combination does not remove perfectly the other signals. This is particularly true with just three channels, and is expected to improve with more channels. We also used simulations to estimate final uncertainties in the SZ signal.

We generate 200 time-stream simulations for each one of the 12 detectors with a combination of sky signal simulations that were projected into a time-line using the BOOMERANG pointing, and a random noise realization with variance consistent with data. As the covariance matrix \( C_{ij} \) of Eq. 1 is built using the cross-spectra between different detectors, the noise realizations include also correlated noise between different detectors. For 145 GHz the noise correlation spectra are reported in Table 7 of Masi et al. (2006) and they are below 3% for the detectors used in the analysis. For the 245 and 345 GHz we measured the noise correlation spectra removing the optimal signal map from the time-ordered data. The correlations are at most 6% for the detectors used in the analysis.

In addition to 200 realizations of primary CMB, the sky signal simulations are computed with Galactic dust, far-Infrared background (FIRB) sources, and radio point sources and combined with BOOMERANG bands passes. The Galactic dust for the observed field is described with model 8 from Finkbeiner et al. (1999), while FIRB and point sources were obtained from the Planck sky model (PSM; Leach et al. 2008; J. Delabrouille 2009, in preparation).

The amplitude of each component in the data was estimated with a Monte Carlo Markov Chain for the three frequencies together. We compared the measured temperature angular power spectrum with a linear combination of CMB, dust, FIRB, and point sources and fitted the amplitude coefficients \( p_\gamma \) of each component \( \gamma \) such that \( C^\text{tot}_\ell = \sum p_\gamma C^\gamma_\ell + N_\ell \), where \( N_\ell \) is detector noise. The CMB amplitude of the predicted model is the same as we find in the data with \( p_{\text{CMB}} = 1.01 \pm 0.04 \). We find \( p_{\text{dust}} = 4.6 \pm 0.8 \), larger than predicted by model 8 of Finkbeiner et al. (1999) and \( p_{\text{radio}} = 0.76 \pm 0.07 \) for radio point sources, smaller than predicted by de Zotti et al. (2005) counts used in PSM, but in agreement with Friedman et al. (2009). The amplitude of the FIRB remains unconstrained with \( 0 < p_{\text{FIRB}} < 0.7 \) (1\( \sigma \)).
Monte Carlo binned power spectra for the SZ pipeline as used for the data. This results in three sets of simulations. The calibration uncertainties of the time-lines were calculated assuming a zero signal. This does not bias the procedure since the optimal weights from Eq. 1 are independent of the exact amplitude of the large-scale SZ effect.

The simulated time-lines have been analyzed with the same pipeline as used for the data. This results in three sets of Monte-Carlo binned power spectra for the SZ $C_{bMC}^{SZ}$, which should, in principle, be zero since the SZ signal is not included in the simulations. From the distribution of each set of $C_{bMC}^{SZ}$ we derived (1) a bias in the SZ binned power spectrum from $(C_{bMC}^{SZ})$ and (2) the bin-to-bin covariance matrix due to statistical noise and sampling variance of the CMB, 

$$C_{bb} = (\langle C_{bMC}^{SZ} \rangle - \langle C_{b'MC}^{SZ} \rangle) \times (\langle C_{bMC}^{SZ} \rangle - \langle C_{b'MC}^{SZ} \rangle).$$

The error bars on the angular power spectrum are given by $\Delta C_{b}^{SZ} = \sqrt{C_{bb}}$. In Table 1 we quote the average value of the bias from the three sets in our residual amplitude and add the average of the dispersion of these residuals as an additional error (Table 1 foreground error).

These foreground errors are combined with the beam errors, which are estimated again through Monte Carlo simulations. The calibration uncertainties of the time-lines were also included through Monte Carlo simulations. They are at most 2%, 8%, and 13% for the 145 GHz, 245 GHz, and 345 GHz, respectively, leading to an error of 4%, 16% and 26% on the temperature angular power spectra at each of the three frequencies. All the uncertainties listed above are added in quadrature for the final SZ band-power uncertainty.

4. SZ POWER SPECTRUM ESTIMATE

In Table 1 we list the values we obtain for the three multipole bins between $\ell = 250$ and 1200. We also list the residual level from each foreground component, including detector noise, and the error associated with various uncertainties as described above. As tabulated, the biggest contamination to SZ detection comes from instrumental noise at the largest angular scales, while the FIRB dominates the contamination at the smallest angular scales probed by the experiment. Radio point sources generate negligible confusion, primarily because at these high frequencies radio sources produce a weaker background compared to the dusty galaxies making the FIRB. In accounting for foreground contamination in the SZ estimate, we have taken a conservative approach here allowing for all components. An aggressive approach with the assumption of no FIRB leads to a marginal detection of an SZ signal especially in the third bin. Though the amplitude of FIRB fluctuations at 350 GHz is uncertain and we have based our model on the PSM, we do not consider an SZ detection with a no FIRB assumption to be realistic.

The binned SZ power spectrum limits at the RJ end of the frequency spectrum are shown in Figure 2, where we plot the 68% confidence level limit for three bins between multipoles of 250 and 1200. In estimating the final SZ band power uncertainty, we also include the usual Gaussian cosmic variance and the extra covariance from the non-Gaussian nature of the SZ power spectrum (Cooray 2001). This covariance is calculated assuming $\sigma_8^{SZ} = 0.95$ and making use of the same halo model as the one used by the WMAP team’s SZ model and shown with a solid line in Fig. 2 (Komatsu et al. 2002). Within this model, we study the cosmological implications of our limit on the SZ fluctuations, using a MCMC package (Lewis & Bridle 2002) to constrain the amplitude of fluctuations. For reference to numerical simulations, with a dashed line, we also show the average SZ signal and the scatter from a set of ten simulations at $\sigma_8 = 1$ from White (2003).

In addition to three bins shown in Figure 2, we also combine the estimation of BOOMERANG SZ power spectrum to a single broad bin of $250 < \ell < 1200$. We find an upper limit of 234 $\mu$K$^2$ in $l(l+1)C_l/2\pi$ at the 95% confidence level. Previous analytical calculations have shown that $C_l^{SZ} \propto (\sigma_8^{SZ})^2(\Omega_b h)^2$ (Seljak et al. 2001), where we separate $\sigma_8^{SZ}$ associated with SZ from the primordial normalization $\sigma_8$. The amplitude constraint from BOOMERANG SZ data alone is $\sigma_8^{SZ} < 1.14$ at 95% confidence level.

In Figure 2, we also compare our upper limits with results on SZ fluctuations in the literature, including CBI (Sievers et al. 2009), BIMA (Dawson et al. 2006), and ACBAR (Reichardt et al. 2008). We scale the ACBAR value from 150 GHz to the RJ end of the spectrum for easy comparison with all other results. We also fit jointly the combined WMAP 5-year (Komatsu et al. 2008), ACBAR (Reichardt et al. 2008), and CBI (Sievers et al. 2009) data together with SZ upper limits from BOOMERANG and SZA. We use the same analytical halo model with $\sigma_8^{SZ} = 0.95$ to include an extra uncertainty associated with non-Gaussian covariance in each of these measurements; these, however, make only a minor difference except in the case of BIMA where the smaller area surveyed increase the importance of non-Gaussianities. Marginalizing over all other cosmological parameters in the $\Lambda$CDM model, we find $\sigma_8^{SZ} < 0.92$ at 95% confidence level ($\sigma_8^{SZ} < 0.71$ at 1$\sigma$). This SZ derived amplitude is fully consistent with WMAP 5-year result with $\sigma_8 = 0.81 \pm 0.02$ (Komatsu et al. 2008). While it has been claimed in the past that the SZ derived $\sigma_8$ is higher than the value derived from the CMB, we do not find this is the case with the BOOMERANG data.

The next opportunities to perform a multi frequency analysis similar to ours will be with Planck and OLIIMPO (Masi et al. 2008). Both these experiments include multiple bands at high frequencies where the SZ is positive. As we have found that only one channel above the SZ null frequency is not adequate to separate both CMB and FIRB from SZ fluctuations, with several high frequency channels, these upcoming CMB experiments should be able to measure and separate FIRB more accurately than we were able to with just one channel at 350 GHz.

We gratefully acknowledge support from NSF CAREER AST-0645427 at UCI. We also acknowledge support from the Italian Space Agency (contracts I/007/06/0 and I/016/07/0), and from Programma Nazionale Ricerche in Antartide. The authors acknowledge the use of the Planck Sky Model, developed by the Component Separation Working Group (WG2) of the Planck Collaboration.
